INDEX OF TREATMENT

First Edition, November, 1907.

Second Edition, with a few minor alterations, January, 1908.

Third Edition, further revised, April, 1908.

Fourth Edition, fully revised, November, 1908.

Fifth Edition, reprint, January, 1910.

Sixth Edition, revised and enlarged, October, 1911.

Reprinted May, 1913.

Seventh Edition, revised and enlarged, November, 1915.

AN
INDEX OF TREATMENT
BY
VARIOUS WRITERS

Edited by

ROBERT HUTCHISON, M.D., F.R.C.P.

Physician to the London Hospital; and Physician (with charge of Out-Patients) to the Hospital for Sick Children, Great Ormond Street;

AND

JAMES SHERREN, F.R.C.S.

Surgeon to the London Hospital; and Senior Surgeon to the Poplar Hospital for Accidents

Revised to conform with American usage by

WARREN COLEMAN, M.D.

*Professor of Clinical Medicine and Applied Pharmacology,
Cornell University Medical College; Visiting Physician
to Bellevue Hospital, New York.*

SEVENTH EDITION, REVISED AND ENLARGED

NEW YORK:
WILLIAM WOOD AND COMPANY
MDCCCXVI

PRINTED IN ENGLAND BY
JOHN WRIGHT AND SONS LTD.,
BRISTOL.

PREFATORY NOTE TO AMERICAN EDITION

As the differences between many British and American pharmaceutical preparations are merely nominal, preparations of the United States Pharmacopœia and National Formulary have been substituted for the British in a number of prescriptions. Where potent drugs are concerned, the dosage has been calculated to American standards or the British preparation has been retained, always indicated by the sign (B.P.). As far as possible the revision has been brought into accord with the forthcoming United States Pharmacopœia.

The text of the English edition has been altered slightly in a few articles. Comments upon the text have taken the form of footnotes.

New York City, October, 1915.

PREFACE TO THE SEVENTH EDITION

IN the present edition all the articles have been thoroughly revised and in many cases re-written. Several new articles have been added, amongst them being those on Sterility, Radium-therapy, and the Psychoneuroses. The Surgical Editorship has now been undertaken by Mr. James Sherren. The Editors and Publishers have once more to express their thanks for many valuable suggestions which have been carefully considered in the process of revision.

THE EDITORS.

London, July, 1915.

PREFACE TO THE FIRST EDITION

THE present work is intended to provide the practitioner with a complete guide to Treatment in moderate compass, and in a form convenient for reference.

The Publishers have been fortunate in securing the co-operation of a group of contributors of special experience, whose names will be a sufficient guarantee of the value of the text, and no pains have been spared to make the book a trustworthy index to the best and most modern methods of dealing with disease.

Care has been taken to avoid embarrassing the reader with a large choice of procedures, and therefore those only have been described which, in the opinion of the respective writers, are considered the simplest and most effective.

In view of the special audience to whom the book is addressed, no attempt has been made in the surgical articles to deal with the more elaborate operations which require special skill for their successful performance; on the other hand, non-operative treatment has been dealt with in detail, as well as such minor or emergency operations as any practitioner may be called upon to perform. The management of labour, whether complicated or uncomplicated, has not been regarded as falling within the legitimate scope of the book.

It is obvious that, in spite of all the care which has been bestowed upon its production, a work such as this is bound to be marked by some omissions. The Editors will therefore gladly welcome suggestions from readers which may enable these to be remedied in future, as well as details of any method of treatment which has been found specially useful in practice, and which is not described in the present edition.

THE EDITORS.

London, November, 1907.

LIST OF CONTRIBUTORS AND THEIR SUBJECTS

JERVOIS AARONS, M.D., M.R.C.P.; Gynæcologist St. Anthony's Hospital, North Cheam; late Registrar to the Hospital for Women, Soho.

Sterility, 986

SIR THOS. CLIFFORD ALBUTT, K.C.B., M.D., LL.D., M.A. Camb., F.R.C.P., F.R.S., etc.; Regius Professor of Physic University of Cambridge.

Arteriosclerosis, 89

H. RUSSELL ANDREWS, M.D., F.R.C.P.; Obstetric Physician London Hospital.

Chorea Gravidarum, 181—Dyspareunia, 275—Kraurosis Vulvæ, 586—Menorrhagia and Metrorrhagia, 630—Pregnancy (Disorders of), 787—Pruritus Vulvæ, 802—Salpingo-oophoritis, 906—Urethral Caruncle, 1062—Uterus (Displacements of), 1074—Vaginismus, 1076

GILBERT A. BANNATYNE, M.D., F.R.C.P.; Consulting Physician Royal Mineral Water Hospital, and Physician Royal United Hospital, Bath.

Rheumatoid Arthritis, 879

FREDERICK E. BATTEN, M.A. Camb., M.D., B.C., F.R.C.P.; Physician Hospital for Sick Children, Great Ormond Street; Physician to Out-patients National Hospital for the Paralyzed and Epileptic.

Migraine, 645—Neuralgia, 701—Neuritis, 715—Palsies (Cerebral, of Childhood), 748—Poliomyelitis (and Acute Encephalitis), 784—Sciatica, 917

VICTOR BONNEY, M.S., M.D., B.SC., F.R.C.S.; Assistant Gynæcological and Obstetric Surgeon Middlesex Hospital; Surgeon Chelsea Hospital for Women.

Puerperal Sepsis, 812

SIR JOHN ROSE BRADFORD, K.C.M.G., D.SC., M.D., F.R.C.P., F.R.S.; Holme Lecturer on Clinical Medicine University College Hospital Medical School, London; Physician University College Hospital and Seamen's Hospital.

Dropsy (Renal) 266—Nephritis (Acute), 667—Phosphaturia, 765

BYROM BRAMWELL, M.D., F.R.C.P.E., LL.D., F.R.S.E.; Senior Ordinary Physician Chalmers' Hospital Edinburgh; Consulting Physician Edinburgh Royal Infirmary.

Heart (Valvular Diseases of), 499

EDWIN BRAMWELL, M.B., F.R.C.P.; Assistant Physician Edinburgh Royal Infirmary.

Disseminated Sclerosis, 265—Epilepsy, 336—Myasthenia Gravis, 656—Paralysis Agitans, 750—Paraplegia, 752—Syphilis of the Nervous System, 1001—Tubes Dorsalis, 1003

JOHN MILNE BRAMWELL, M.B., C.M.

Hypnotism (Treatment by), 534

CHARLES W. BUCKLEY, M.D.; Hon. Physician Devonshire Hospital and Buxton Bath Charity.

Hydrotherapy, 524

J. LEMARE BUNCH, M.D., D.SC., M.R.C.P.; Physician in Charge of Skin Department Queen's Hospital for Children.

Pruritus, 798

JAMES CALVERT, M.D., F.R.C.P.; Physician and Joint Lecturer on Medicine St. Bartholomew's Hospital; Physician Royal Hospital for Diseases of the Chest.

Prescribing, 788

HARRY CAMPBELL, M.D., F.R.C.P.; Physician West End Hospital for Nervous Diseases; Late Physician North-West London Hospital.

Headache, 483

CHARLES W. CATHCART, M.A., M.B., F.R.C.S.; Surgeon Royal Infirmary, Edinburgh.

Fractures, 387

GEORGE CLARK CATHCART, M.A., M.D., C.M.; Surgeon London Throat Hospital. Adenoids, 10—Laryngitis, 593—Pharyngitis, 759—Tonsillitis, 1040

ARTHUR HENRY CHEATLE, F.R.C.S.; Lecturer on Aural Surgery and Aural Surgeon King's College Hospital.

Ear (Affections of), 282

WM. HENRY CLAYTON-GREENE, M.B., C.M. Camb., F.R.C.S.; Lecturer on Surgery St. Mary's Hospital Medical School; Surgeon St. Mary's Hospital and French Hospital.

Abscess, 3—Arthritis (Suppurative), 97—Boils, 113—Burns and Scalds, 145—Carbuncle, 162—Erysipelas, 345—Ganglion, 413—Gangrene, 414—Septicæmia and Pyæmia, 924—Tetanus, 1027—Toe-nail (Ingrowing), 1039—Tuberculous Glands, 1048—Ulcers, 1057—Warts, 1085—Whitlow, 1086

SIR THOMAS SMITH CLOUSTON, M.D., F.R.C.P.E. (The Late).

Mental Diseases, 634

HENRY CURTIS, B.S., F.R.C.S.; Surgeon Metropolitan Hospital.

Salivary Glands (Affections of), 901

CHAS. WILBERFORCE DANIELS, M.B. Camb., M.R.C.S., F.R.C.P.; Lecturer and Late Director London School of Tropical Medicine.

Anæmia (Tropical), 36—Beri-beri, 103—Bilharzia, 110—Blackwater Fever, 112—Cholera, 177—Delhi Boil, 234—Dengue Fever, 234—Diarrhœa (Hill) 242—Diarrhœa (Tropical), 248—Dysentery, 273—Filariasis, 365—Hepatitis, 516—Leprosy, 601—Malaria, 614—Mosquito Bites, 647—Phlebotomus Fever, 764—Plague, 768—Relapsing Fever, 864—Sprue, 975—Sunstroke, 993—Trypanosomiasis, 1047—Undulant Fever, 1059—Yaws, 1099—Yellow Fever, 1099

DAVID DRUMMOND, M.A., M.D., D.C.L.; Consulting Physician Royal Victoria Infirmary, Newcastle-on-Tyne; Joint Professor of Medicine University of Durham College of Medicine.

Aneurysm (Thoracic), 60

THOS. CRISP ENGLISH, M.B., B.S., F.R.C.S.; Surgeon and Lecturer on Surgery St. George's Hospital.

Biliary Fistula, 110—Breast (Neuralgia of), 127—Breast Tumours, 128—Breasts (Hypertrophy of), 135—Gall-stones (Surgical Treatment of), 412—Hepatic Abscess, 515—Liver (Hydatid Disease of), 604—Liver (Injuries of), 604—Mammary Abscess, 617—Mastitis, 622—Nipple (Diseases of), 719

HAROLD A. T. FAIRBANK, M.B., M.S., F.R.C.S.; Surgeon to In-patients Hospital for Sick Children, Great Ormond Street; Orthopædic Surgeon Charing Cross Hospital; Surgeon Miller Hospital.

Balanitis, 102—Paraphimosis, 752—Phimosis, 761—Synovitis (Traumatic), 994—Talipes (Congenital), 1014

EDWARD WILBERFORCE GOODALL, M.D., B.S.; Medical Superintendent Eastern Hospital, Homerton.

Anthrax, 74—Chicken-pox, 173—Diphtheria, 249—Fever (Acute Infectious), 358—Glanders, 423—Influenza, 522—Measles, 623—Meningitis (Epidemic Cerebro-spinal), 626—Mumps, 655—Scarlet Fever, 909—Small-pox, 932—Typhoid Fever, 1054—Typhus Fever, 1057

SIR ALFRED PEARCE GOULD, K.C.V.O., M.S., F.R.C.S.; Senior Surgeon and Surgeon-in-Charge Out-patients Cancer Department Middlesex Hospital.

Cancer (General Treatment of Patients suffering from) 154

WM. JOHN GOW, M.D., F.R.C.P.; Obstetric Surgeon St. Mary's Hospital.

Abortion, 2—Amenorrhœa, 19—Dysmenorrhœa, 274—Endometritis (Chronic), 330—Fibroids of Uterus, 364—Hæmorrhage (Uterine), 470—Leucorrhœa, 601

GEO. LOVELL GULLAND, M.D., F.R.C.P.E.; Professor of Medicine University of Edinburgh; Physician Royal Infirmary, Edinburgh.

Hæmophilia, 465—Leukæmia, 602—Lymphadenoma, 613—Splenic Anæmia, 965

LEONARD G. GUTHRIE, M.A. ONOR., M.D., F.R.C.P.; Physician Hospital for Epilepsy and Paralysis, Maida Vale, and Paddington Green Children's Hospital.

Albuminuria (Orthostatic, Cyclical, or Functional), 15—Aphasia, 76—Apoplexy, 77—Chloroform Poisoning (Delayed), 174—Chorea (Chronic), 180—Convulsions (Infantile), 216—Enuresis (in Childhood), 331—Hemiplegia, 508—Laryngeal Stridor, 592—Laryngismus in Childhood, 593—Myoclonus, 655—Night Terrors 718—Nystagmus and Head-nodding, 734—Tetany in Childhood, 1030—Vomiting (Cyclical), 1081

WILFRED J. HADLEY, M.D., F.R.C.P.; Physician, Pathologist, and Lecturer in Medicine London Hospital; Physician City of London Hospital for Diseases of the Chest.

Asthma (Bronchial), 98—Bronchiectasis, 135—Bronchopneumonia (Catarrhal), 143—Pleurisy, 769—Pneumonia, 773

WM. ILBERT HANCOCK, F.R.C.S. (The Late). (Revised by W. T. LISTER.)⁴

Episcleritis, 343—Eyelids (Diseases of), 353—Iritis, 559—Lacrymal Apparatus (Diseases of), 587—Ophthalmia (Sympathetic), 743—Orbital Cellulitis, 745

JOHN HAY, M.D., M.R.C.P.; Senior Assistant Physician Royal Infirmary, Liverpool.

Bradycardia, 124—Heart (Irregularity of), 497—Palpitation, 746—Tachycardia, 1007

THOMAS J. HORDER, M.D., B.S.C., F.R.C.P.; Medical Registrar and Demonstrator of Morbid Anatomy St. Bartholomew's Hospital; Physician Great Northern Central Hospital; Physician Cancer Hospital, Fulham.

Specific Therapy (Bacteriotherapeutics), 934

WILLIAM HUNTER, M.D., F.R.C.P.; Physician London Fever Hospital; Senior Assistant Physician and Lecturer on Pathology Charing Cross Hospital.

Anæmia, 19—Purpura, 840

ROBERT HUTCHISON, M.D., F.R.C.P.; Physician London Hospital, and Physician (with charge of Out-patients) to the Hospital for Sick Children, Great Ormond Street.

Acidosis, 7—Acromegaly, 7—Acroparæsthesia, 7—Borborygmi, 124—Breath (Offensive), 135—Chilblains, 174—Colitis, 191—Congenital Pyloric Stenosis, 198—Croup, 224—Diabetes Insipidus, 235—Diabetes Mellitus, 235—Diarrhœa (Chronic), 240—Drowned (Treatment of the Apparently), 268—Duodenal Ulcer, 270—Dyspepsia, 276—Dyspepsia (in Childhood), 281—Erythromelalgia, 347—Gastroptosis, 422—Gastrostaxis, 423—Glycosuria, 428—Hiccough, 520—Lumbar Puncture, 607—Marasmus, 618—Meningitis (Posterior Basic), 629—Menopause, 629—Nightmare, 719—Nose (Redness of), 729—Obesity, 734—Osteomalacia, 745—Oxaluria, 746—Peritonitis (Tuberculous), 758—Perspiration (Offensive), 759—Poisoning, 779—Priapism, 794—Raynaud's Disease, 860—Scurvy, 922—Scurvy (Infantile), 923—Sea-sickness, 923—Thrush, 1036—Uric Acid Gravel, 1068—Urticaria, 1073—Vulvo-vaginitis, 1085—Worms (Intestinal), 1092

ROBERT JONES, F.R.C.S.; Hon. Surgeon Royal Southern Hospital, Liverpool; Surgeon Royal Liverpool Country Hospital for Children, Heswall, Cheshire.

Congenital Dislocation of the Hip, 197—Dupuytren's Contraction of the Palmar Fascia, 272—Flat-foot (Weak Foot, Everted Foot), 365—Hallux Rigidus, 478—Hallux Valgus and Bunion, 478—Hammer-toe, 479—Knock-knee, 585—Scoliosis, 919—Spina Bifida, 957—Talipes (Acquired), 1009—Volkmann's Ischæmic Paralysis, 1080

HARRY LAMBERT LACK, M.D., F.R.C.S.; Surgeon Throat Department, and Lecturer on Diseases of the Throat London Hospital; Consulting Surgeon Hospital for Diseases of the Throat, Golden Square.

AN

INDEX OF TREATMENT

ABDOMINAL INJURIES.—The traumatic group fall into two divisions, those with penetrating wounds, and the subcutaneous. In the former, which are rare in civil practice, immediate operation is the rule. The wound should be explored layer by layer, after it and the surrounding area have been painted with a solution of 2 per cent iodine in rectified spirit, or tincture of iodine. Its depth should not be investigated by probing. The wound should be excised if it is a lacerated one, or if the weapon inflicting it is infected. It should be closed in layers, and in most cases drained by tube for twenty-four hours. If the peritoneal cavity has been opened, the presence of blood or the contents of any of the hollow viscera may point to intraperitoneal damage. If, as is often the case, this is absent, the condition of structures lying immediately beneath the wound should be investigated, remembering that wounds penetrating hollow viscera frequently cause more than one injury. Lives have been lost through forgetfulness of this, one wound having been sutured, while death has occurred by leakage from one overlooked.

In subcutaneous injuries, signs and symptoms may leave no doubt that surgical intervention is necessary: for example, signs of trauma over the ribs on the right or left side with symptoms of concealed hæmorrhage pointing to rupture of the liver or spleen; a frequent desire to micturate, nothing passing except perhaps a little blood, suggesting rupture of the bladder. (In this connection I would urge you to neglect the methods of examination given in many text-books, —the passage of instruments, or attempts to fill the bladder with air or fluid. No instrument should ever be introduced in a case of suspected rupture of the bladder; the risk of infection is enormous, and no certain information can be obtained. If a rupture of the bladder is suspected, abdominal exploration should be carried out.) Again, after an injury to this region, the formation of a swelling in the loin, gradually increasing in size, often associated with hæmaturia and considerable vomiting, indicates a ruptured kidney.

But the signs are not usually so definite as this. The patient's condition has to be carefully watched. After systematic examination, an hourly pulse and temperature chart should be kept; if the pulse-rate tends to rise steadily, exploration should be undertaken. It is only in this way that disasters can be avoided. Every case of abdominal injury, no matter how trivial it appears, should be taken into hospital or sent to bed and carefully watched. Many cases of ruptured gut are well enough, immediately after the accident, to walk to medical aid. Abdominal rigidity and a rising pulse-rate are the most important signs.

Spleen.—In many cases of ruptured spleen the bleeding is profuse. Immediately on opening the abdomen the pedicle should be seized and the bleeding controlled by forceps. After this has been done, the extent of the damage can be investigated, the pedicle ligatured, and the spleen removed; it is rarely possible to save it.

Liver.—The bleeding should be controlled by catgut sutures passed through the liver substance at some distance from the injury; by gauze packing; or by both combined.

Kidney.—In cases of renal injuries associated with the formation of a swelling in the loin, operation should not be delayed. It may be possible to save the viscus if exploration is early. Rents of the substance of the kidney may be sutured, and the wound drained. Where the crushing is extensive, or involves the pelvis or ureter, nephrectomy should be carried out. *James Sherren.*

ABORTION.—For the purposes of treatment, abortion may be divided into (1) Threatened; (2) Inevitable. The signs of threatened abortion are bleeding and pains, or there may be bleeding without pains. The pains are similar to those of the first stage of labour, but less severe. If the membranes have ruptured or the os is nearly fully dilated, abortion may be regarded as inevitable. In early abortion the ovum is sometimes entirely pushed out of the uterus into the distended cervical canal before the os externum has begun to dilate. In such cases likewise the abortion is inevitable.

1. **Threatened Abortion.**—In all cases absolute rest in bed is essential. No treatment is effective when this precaution is neglected. The patient should be kept strictly in the recumbent position. If there is bleeding but no pain, small doses of ergot may be given. If there are pains as well as bleeding, it is better to give small doses of opium. *Extractum viburnum prunifolium* in 3-gr. doses may be given in the form of a pill three times a day. If given in the form of the fluid extract it should be enclosed in capsules, as it is very disagreeable to take. The treatment should be persisted in for at least a week after the symptoms have subsided. If in spite of treatment the bleeding becomes severe, abortion must be induced.

2. **Inevitable Abortion.**—If the pains are good and the bleeding is not excessive, no interference is necessary. It is most important to examine everything that comes away, to make sure that the abortion is complete. In an early abortion the ovum may be expelled entire, but at the end of the third month the foetus often escapes first, whilst the placenta is retained in the uterus. If nothing is done the placenta may remain undelivered for a week or more, when it will probably decompose. Serious pelvic inflammation, with or without the formation of an abscess, is likely to result from such neglect. If the whole or part of the placenta has been retained, it is absolutely necessary that it be removed at once. To do this is easy if an anæsthetic be given. Strict antiseptic precautions must be taken. No instruments are necessary. The placenta can be detached and removed best by the fingers of the right hand, whilst the left hand pushes the uterus down so as to enable the fingers of the internal hand to reach the fundus. If at the time of removal the placenta is infected, as indicated by an odour of decomposition or the existence of fever, its removal is attended by a serious risk to the patient of a general septicæmia. In these cases the uterus should be irrigated with a lysol solution immediately after removal, and a prophylactic injection of a stock vaccine of a million streptococci should be given, and repeated every other day until she has had three doses.

If the process of abortion be very slow, or if in the course of it the bleeding becomes excessive, it will be necessary to expedite matters. If the cervix be imperfectly dilated, the best treatment is to introduce one or more sterile laminaria tents into the cervical canal, and leave them in position for twelve hours. If the dilatation has then progressed sufficiently, the uterus may be emptied by the finger. Rapid dilatation with Hegar's dilators is sometimes, but not often, to be preferred. In inevitable abortion ergot should not be given until the uterus has been emptied.

It cannot be too carefully borne in mind that, unless special indications exist, there is no more necessity to interfere in the course of a normal abortion than there is in the course of a normal labour. A certain amount of bleeding is a necessary accompaniment of every abortion, and no alarm need be felt unless it is excessive.

After an abortion the patient should be advised to lie in bed for at least a week. No douches are necessary.

W. J. Gow.

ABSCESS.—The localized collection of pus to which the term abscess has been given is in all cases treated by incision. At the same time it is necessary to recognize certain stages in the formation of the abscess which have some bearing upon treatment, and further, the steps that should be taken to provide adequate drainage and healing.

When an infective process, upon which the formation of an abscess depends, occurs in a superficial region, steps may be taken to cut short the development of the suppuration, as for example in cases of cellulitis and diffuse phlegmons. Free incisions, in such circumstances, followed as they are by the exit of the toxins and by the advent of protective and immunizing lymph to the infected area, are beneficial and advisable; but when the source of trouble lies at some distance from the surface, and where perhaps from the anatomical relations of the part it is desirable to give nature a chance either of effecting resolution of the inflammatory exudate or of determining it into a definite abscess, local applications—fomentations or hot irrigations—are to be employed.

As soon as pus has made its presence manifest, either by the phenomenon of fluctuation or by a softening or boggy in an area of induration, no time should be lost in giving it a ready exit. All abscesses should be opened as soon as they have declared themselves; and they should be opened freely, with due respect to the anatomy of the part concerned, and in such a position that drainage of the contents is favoured.

If important structures are likely to be encountered or injured, Hilton's method should be employed: this consists in incising the tissues down to the deep fascia, and inserting a director into the most prominent part of the swelling, or where fluctuation is most obvious, until the pus flows along the groove. The opening is then enlarged with sinus forceps or Spencer Wells forceps, until a track of sufficient size has been established. When once the opening has been made, it is usually unnecessary to do more than insert a drainage tube, so that the discharge may find a ready exit. There is no great objection to the irrigation of the cavity with weak antiseptics, though it does no more than wash away the clot which has collected in the cavity. Strong antiseptics and scraping of the cavity wall are in most cases injurious, since the protective barrier of granulation tissue is damaged, fresh lymphatic spaces are opened up, and young vessels are torn across. The necrotic material which often lies against the granulation tissue wall is soon cast off, and can be gently syringed away at the daily dressing. Scraping and strong antiseptics do not facilitate its separation.

Drainage.—All abscesses require drainage, though the duration and form of this drainage vary in individual cases. The object is twofold: first, to allow the necrotic tissue, which must separate from the healthy granulations, to come away; secondly, to prevent the superficial opening from closing before the deeper parts have become clean and healthy. Two chief agents are in vogue for procuring drainage, viz., strips of gauze and rubber tubes (occasionally glass); sometimes both are combined. Generally a rubber tube of fair size (for the purpose of draining an abscess of any size no tube smaller than a cigarette should be employed) is the best, but where the bleeding is profuse, or where the position of the abscess is unsuitable for tube drainage, as in ischiorectal

abscess, gauze may be substituted. In such cases care should be taken that the gauze is not tightly packed into the cavity, as this prevents shrinkage and contraction, which are essential for healing. Light packing, which can readily be removed, is all that is required.

During the subsequent progress of the case, irrigations of the cavity through the tube once or twice daily are of value, the tubes being gradually shortened as the cavity closes. With regard to the irrigation, it is worth remarking that peroxide of hydrogen, though a remedy of undoubted value, and frequently employed in these cases, must be used with the utmost caution. When brought into contact with blood or proteid matter the oxygen is given off freely, and if it be injected into a cavity from which there is not a very ready exit, the gas so generated may force its way through the walls of the abscess into the cellular tissue, causing serious complications. Drainage should not be too prolonged, since the presence of a tube or strip of gauze is a source of irritation, and sinuses are often caused by a too zealous adherence to the tube over a long period. When the temperature has been normal for four or five days, and the discharge has become clean, thin, and sweet, it is time to think of withdrawing the drain. No definite rules can be laid down, but provided that the superficial opening is kept patent by a small plug, it is often very advantageous to remove the drainage early.

Rest is an important factor in the healing of abscesses. Neglect of this detail is another cause of troublesome sinuses. The part should be immobilized as far as possible. Splints, bandages, or whatever apparatus may be most suitable, should be applied, and, in cases where the conditions of the part permit, gentle pressure will assist the natural process of contraction and obliteration of the cavity.

Axillary Abscess usually arises from suppuration in the cellular tissue or glands of the axilla. The abscess lies beneath the deep fascia, and should be opened by a vertical incision on the inner axillary wall in order to avoid important structures, and the pus should be reached by Hilton's method.

Submaxillary Abscess arises either from suppuration in the submaxillary lymphatic glands or as the result of a cellulitis. Cellulitis in this region is especially serious, owing to the risk of œdema of the glottis supervening. This œdema, which occurs in the aryteno-epiglottidean folds, causes occlusion of the superior aperture of the larynx, and fatal dyspnœa often follows an attempt to anesthetize the patient. In no instance is the beneficial effect of incisions into the indurated area of a cellulitis more marked than in Ludwig's angina (q.v.). The incisions may be made either parallel with and under cover of the border of the lower jaw, or vertically in the median line; and if there be dyspnœa when the patient comes under treatment, local anæsthesia alone should be employed.

Ischiorectal Abscess occurs after infection of the fat in the ischiorectal fossa, the infection passing in from the bowel, either through a gross abrasion, such as may be produced by a foreign body, or ulcer, or by means of lymphatic communication. There are two well-recognized varieties of ischiorectal abscess: the acute form, caused in most instances by the *Bacillus coli* or other pyogenic organisms; and the tuberculous. The ordinary variety is treated by free incisions, which should extend widely across the buttock at right angles to the anus, and in most cases it is advisable to make crucial incisions over the centre of the fossa, removing subsequently all undermined skin; the finger should then be introduced and all loculi broken into. The cavity should be lightly packed with gauze and allowed to granulate from the bottom.

Cases of ischiorectal, and for the matter of that anal, abscesses, illustrate the importance of rest in order that perfect healing may be secured. The common

result of these abscesses is that after they have discharged their contents a sinus or fistula is formed, owing to the movement of the part and the bad circulation, and a subsequent operation is necessary to effect its cure. For this reason it has been advocated that in all such cases the external sphincter should be divided, and the abscess cavity made continuous with the lumen of the anus, so that the frequent contractions of this muscle shall not interfere with the healing process. This treatment is advisable if, at the time of active treatment, a fistulous communication with the bowel is evident, but it is unwise as a routine. If the patient is kept rigidly in bed, lying for the most part on the face or opposite side, healing may occur perfectly. In no circumstance should he be allowed to get up until a thorough trial of rest has been made. If this treatment be combined with daily dressing and the application of lotio rubra and stimulating injections, in a fair proportion of cases the formation of a fistula may be avoided.

The treatment of the tuberculous variety is conducted on the same principles, but it is often advisable to scrape out the walls of the cavity after the pus has escaped. As a rule the simpler the operation the better in these cases, and as soon as possible the patient should be sent away to the seaside, while those remedies which are of value in combating tuberculosis elsewhere should be actively employed.

Anal Abscess may be described as a modification of the ischiorectal variety. It is much commoner, and arises from infection of the sebaceous glands and lymphoid tissue which surround the anal orifice.

The treatment should be conducted on precisely similar lines to those used in the former variety, and later, if necessary, any fistula can be dealt with.

Mammary Abscess.—There are three recognized varieties of mammary abscess: the *superficial*, which is no more than a subcutaneous collection of pus of slight extent; the *intramammary*, which results from an infection spreading into the breast, along the lymphatics or ducts, from a cracked nipple which has been neglected; and the *submammary*, usually a chronic variety dependent upon caries of the rib, the exciting organism being either the tubercle bacillus or the bacillus of typhoid fever.

Under the above heading, only the intramammary form will be discussed.

During the early weeks of lactation, the breast becomes swollen, painful, and red. The abscess presents in one of the quadrants, and should be opened by incisions which radiate out from the nipple. Mere incision is, however, inadequate in these cases. Owing to the tendency of the pus to burrow into adjacent loculi, the finger should be introduced into the abscess cavity, and all secondary communications freely opened up. If there is pocketing in a downward direction, a counter-opening should be made in the costomammary sulcus. Tubes should be employed for from four days to a week, and the breast should be carefully supported by means of a bandage. (See also MASTITIS.)

Palmar and Plantar Abscesses are caused by punctured wounds, or as the result of a spreading whitlow. They should be opened by free longitudinal incisions, but the position of the arterial arches should be carefully borne in mind, since hæmorrhage in wounds of this kind is troublesome and often serious. If the pus has tracked back through the interosseous spaces, a counter-opening should be made on the dorsum. After incision the whole limb should be placed on a splint and kept at rest; but as soon as the temperature is normal and the wounds are healthy, careful movement of the fingers should be undertaken to diminish the stiffness, a usual sequela from the adhesions which have formed in the synovial coverings of the tendons.

Peritonsillar Abscess or **Quinsy** is the usual termination of the parenchymatous form of tonsillitis. The pus is formed outside the tonsil, and this gland is

pushed towards, often across, the middle line by the exudation. The abscess cavity lies between the tonsil and the superior constrictor, and while the tonsil has been thrust in on the one hand, the internal carotid and the ascending pharyngeal arteries have been displaced outwards on the other. Pus can be detected by a feeling of softening external to the tonsil. In most cases no actual fluctuation can be felt.

Although the opening of a peritonsillar abscess is a simple proceeding, it has on many occasions been attended with serious results. In the first place, no general anæsthetic should be employed, as there is great risk, if the patient is anæsthetized, of the pus running down the larynx after the abscess has been opened. A 10 per cent solution of cocaine should be painted over the back of the throat, and the patient should sit or stand facing a good light. The mouth should be opened as widely as possible, though here the operator will experience difficulty, as the inflammation round a tonsillar abscess often prevents the patient from separating his teeth for more than a half to one inch.

The tongue should be depressed, and the fold formed by the anterior pillar of the fauces be clearly defined. The pus lies immediately behind this fold. A narrow scalpel is taken, guarded to within half an inch of the point with strapping. It is introduced on a level with the soft palate, a cut is made downwards for at least half an inch, and the knife is withdrawn. If the opening is not of sufficient size it should be enlarged with sinus forceps. The patient should be instructed to gargle his mouth repeatedly with hot alkaline solutions, and general tonics and quinine should be administered.

Before leaving the subject it will be well to enumerate some of the dangers, errors, and difficulties in performing this operation. Aneurysm of the internal carotid has been mistaken for a quinsy, and on one occasion it was incised in an out-patient department. Sarcoma of the tonsil appears very like quinsy, but inflammatory signs are absent, the temperature is normal, the glands are enlarged and not tender, and the mouth can be freely opened. The tonsil should not be incised; this mistake causes considerable pain, and the pus is missed. The internal carotid has been wounded by a careless use of the knife, and some surgeons prefer a pair of sinus forceps instead of the scalpel for the purpose of evacuating the pus, but if the above directions be followed there is little risk of this untoward accident.

Subphrenic Abscess.—(See separate article.)

Cerebral Abscess.—(See separate article.)

W. H. Clayton-Greene

ACHYLIA (Anacid Dyspepsia).—The treatment of this condition aims at securing the passage of food as soon as possible into the bowel, where digestion can be effected. The food should therefore be finely divided and thoroughly chewed. Perhaps the best thing is to give the following acid mixture after meals, in order to disinfect the gastric contents, and to stimulate the stomach to discharge its contents:—

R	Acidi Nitrohydrochlorici Diluti	Succi Taraxaci (B.P.)	℥j
	Tincturæ Nucis Vomiceæ āā ℥xxv	Aquæ	q.s. ad ̄j

Two tablespoonfuls three times a day directly after meals.

Acidol (betain hydrochlorate) splits in the stomach into betain and hydrochloric acid; it is a means of giving relatively large doses of hydrochloric acid; it is sold in powder or pastilles, alone or combined with pepsin. Two drachms of dilute hydrochloric acid may be administered in half a pint of well-sweetened water or weak infusion of quassia, and as much as a pint of this mixture may be drunk during the meal (Leo).

Robert Saundby.

ACIDOSIS.—Cases of acidosis and acetonæmia, from whatever cause arising, are to be treated on the same lines as a case of diabetic coma (see **DIABETES**), the most urgent need being the introduction into the circulation of large quantities of bicarbonate of soda, both by the mouth and rectum. (See also **VOMITING**, **CYCLICAL**.)

Robert Hutchison.

ACNE VULGARIS.—The treatment of this disease depends on the stage which the individual case has reached. In those cases where “blackheads” are numerous and pustules few, the patient should bathe the face with warm water and apply a sulphur soap, with vigorous friction, for five or six nights a week. The acne skin is greasy, and surprisingly tolerant of irritation, and if the comedones are numerous, one may even recommend the occasional use of a sand soap, such as the famous “Monkey Brand.” The friction is an important part of the treatment, for the skin is anæmic and the cutaneous muscles have lost tone, and the hyperæmia which friction causes and the massage of the muscles are both beneficial. In cases where pustules are present, the same treatment may be used less vigorously, unless the reaction is so great as to induce one to apply a soothing lotion for a few days, e.g. :—

R Sulphuris Præcipitati	3ss	Glycerini	3j
Calaminæ		Aquam	ad 3iv
Zinci Oxidi	āā 3ij		

The pustules, and still more the deeper abscesses which are so commonly present in severe cases, should be opened, and their contents evacuated; but it is not necessary to apply strong antiseptics to their cavities, for these usually heal up readily.

Electricity, in the form of high-frequency currents and x-rays, is surprisingly successful in some cases of acne, but in others is most disappointing.

In about 10 per cent of the cases, or probably less, much improvement follows the administration of the sulphide of calcium, $\frac{1}{8}$ gr. thrice daily; and similar benefit also results in others from the administration of yeast, levurine, or nucleinic acid.

Vaccines of the acne bacillus, either alone or combined with mixed staphylococcal vaccine, will generally hasten the rapidity of the cure. It is not reasonable to expect to cure acne by the injection of staphylococcal vaccine alone.

There is much difference of opinion as to the value of vaccines, and still more as to the proper dose. Some give large doses, others moderate, and yet others small ones; some give them at short and others at long intervals. Some use them in every case, others are very sceptical as to whether they are of any use at all. Without presuming to decide between these conflicting views, it is right to state that my own practice is to give doses of six to ten million at intervals of from ten to fourteen days. More harm seems to result from too frequent than from too large doses.

The diet in acne should be simple, and fats should be taken in moderation; and the usually greasy scalp should be washed frequently.

Norman Walker.

ACORIA, or absence of the feeling of satiety, often associated with obesity, should be treated by regulating the quantity of food taken.

Robert Saundby.

ACROMEGLALY.—The use of pituitary extract in this condition has proved disappointing. Thyroid preparations are worth a trial, as some cases have improved to a certain extent under their use.

Robert Hutchison.

ACROPARÆSTHESIA.—This condition is characterized by a feeling, which is worse at night, of numbness, tingling, burning, etc., in the hands and arms,

and sometimes also in the legs. There are no objective signs. Women about the menopause are most frequently attacked.

TREATMENT consists in avoiding any work which aggravates the sensations (especially washing), in attention to the general health, and in the administration of tonics. Bromides are specially useful, given either at bed-time or in divided doses throughout the day. Small doses of nitroglycerin may be given along with them. Locally, galvanism gives good results. A.B.C. liniment (aconite, belladonna and chloroform liniments B.P. equal parts) may be applied to the hands and arms on going to bed. (See also MENOPAUSE.) *Robert Hutchison.*

ACTINOMYCOSIS.—This disease most commonly attacks the floor of the mouth or the lower jaw, in both human beings and animals; but in recent years it has been recognized with increased frequency in the abdomen in connection with the appendix, in the chest as the cause of chronic pulmonary disease, and has also been proved to attack the genito-urinary system and the skin. The diagnosis is made clinically by the presence of minute granules in the discharge; commonly they are greyish in colour, but may be yellow or red, and under the microscope can be seen to contain the typical ray-fungus.

TREATMENT.—1. The administration of potassium iodide internally has been the orthodox treatment for some years. It may have to be given in increasing doses up to 200 grains a day. It should be well diluted, and although it is depressing, sodium iodide and ammonium iodide are very expensive, and do not seem to have the same effect. We must remember that the organism will grow in a 1 per cent solution of potassium iodide. The drug seems to be useless in pulmonary actinomycosis.

2. Copper sulphate is given (a) Internally, in the dose of a quarter of a grain three times a day; and (b) By irrigation. A one per cent solution seems to have a more beneficial effect on sinuses than does the iodide of potassium. Copper sulphate certainly is very effective against the fungus in connection with barley. In France it is said that two to eight grains per day can be taken by an adult for months without harm.

3. A one per cent solution of iodopin has been tried, and has resulted in cure.

4. X rays locally seem to have a definite curative effect.

5. Specific therapy has been tried, but is too recent; still the prognosis is so bad in internal lesions that this treatment certainly ought to be given a chance.

6. *Surgical treatment.* The lesions in connection with the jaw or the floor of the mouth must be thoroughly opened up, masses of infiltrated tissue cut away, and pockets scraped with a sharp spoon. The freer the surgical treatment, the better the prognosis.

The other actinomycotic lesion coming to the surgeon is in the right iliac fossa. It may be discovered in the routine examination of a removed appendix, but more commonly the patient comes with a mass of fibrous tissue, sinuses, and infiltrated skin in the right iliac fossa. Intestinal obstruction is very rare, although the disease may be originating in the colon rather than the appendix. The mass is too hopelessly adherent to attempt removal; but the part may be put at rest by a short-circuiting operation between the small and large gut, and then the lesion in the right iliac fossa treated by free scraping of the sinuses and injection of iodoform emulsion. (See also SALIVARY GLANDS, AFFECTIONS OF; and JAW, NECROSIS OF.)

Robert Milne.

ADDISONIAN ANÆMIA.—(See ANÆMIA.)

ADDISON'S DISEASE.—Treatment must be considered under two headings: (1) *Specific*; (2) *Symptomatic*.

1. Specific Treatment.—It is now generally accepted that the symptoms of Addison's disease result from impairment and, eventually, complete suppression, of the functions of the suprarenal capsules, brought about by disease of the capsules themselves, or of the nerve tracts controlling their function. This suprarenal inadequacy can be actively atoned for only by the administration of its physiological equivalent. In every case, therefore, suprarenal gland substance should be administered. It must be frankly admitted that, so far, the results reported are somewhat disappointing. In some cases there has been no perceptible improvement; in others but temporary benefit has followed; while in some instances remarkably good results have been obtained. These discordances are not difficult to understand; it must be remembered that the exact lesion varies in different cases, that the diagnosis is always difficult, and that too often it is established only at a hopelessly late period of the disease. Moreover, at present we have not learned how to prepare, much less how to administer, suprarenal substance of certain standardized physiological activity. Up to the present the gland substance has usually been given by the mouth, and the suprarenals of sheep have been mostly employed. Tablets of dried extract are prepared, 1 gr. of which corresponds to 15 gr. of the gland substance. Treatment should be begun by one tablet thrice daily, and the dose steadily increased.

So far no bad results have been recorded, though several drachms of gland substance are said to have been given daily with benefit. The treatment should be persisted in, and not remitted when improvement, however well marked, takes place.

If mouth administration fails, hypodermic injections of adrenalin chloride (1-1000) may be tried: fifteen drops, cautiously increased to thirty drops, once daily, should be given for a period of four to six weeks at a time, and the effect on the blood-pressure noted.

Since in most cases of Addison's disease the destruction of the suprarenals is brought about by caseous tuberculous deposits, injections of tuberculin, with a view to the fibrosis of such deposits, has been advocated. In some instances improvement has followed their use. It is wise to begin with a small dose such as $\frac{1}{20000}$ of B.E. once weekly, and steadily increase this to $\frac{1}{2000}$.

2. Symptomatic Treatment.—The duration of life in Addison's disease varies from a few days to some years. These wide limits depend, to some extent, on the nature of the destructive agency at work, but probably the difficulty of diagnosis is an important factor. Only too often the cases are seen in the last stages of the characteristic asthenia, when no treatment is of avail. When seen earlier, general treatment is of great importance. The patient must give up all active work, and be content to lead a restricted life, free from all worry and stress. Fresh air and sunshine are of great value. All muscular exertion must be moderate, and if there are any signs of faintness or syncope, he should spend most of his time in the horizontal position.

The diet should be plain, but not too restricted, and meat should be allowed; stimulants are not to be regarded as a necessity for all cases. Sooner or later vomiting usually occurs; the diet must then be regulated, and liquid or pre-digested foods given; iced champagne in small quantities is useful. Medicinally, bismuth, oxalate of cerium, and iodine may be tried.

R Elixir Bismuthi (N.F.)	℥xxx	Tincturæ Cardamomi Compositæ	℥x
Acidi Hydrocyanici Diluti	℥iij	Aquæ Menthæ Piperitæ	q.s. ad ℥ss

Every three hours.

Thrice daily in water after meals.

Lewis Smith.

ADENOIDS.—Adenoid growths may require treatment at all ages, the youngest age at which the writer has operated being four months, and the oldest forty-two years.

In considering the diagnosis of enlarged tonsils and adenoids it should be remembered that while the two conditions usually co-exist, yet the former may be present without any hypertrophy of the lymphoid tissue of the posterior nares, while in other cases adenoids may be present without any enlargement of the faucial tonsils. The writer never makes a digital examination of the posterior nares. It is a painful proceeding and extremely terrifying to a nervous child. Moreover the information afforded by this method of examination is often incomplete, for in restless children the examining finger frequently misses the hypertrophied masses which lie in close proximity to the Eustachian tubes and produce the deafness which is one of the most distressing symptoms of the affection.

In those cases where the faucial tonsils are hypertrophied, there is no necessity to examine for adenoids; for this examination may be made when the patient is under the anæsthetic, and if present the growths can be removed at the same time as the tonsils. When, however, the faucial tonsils are not enlarged, the diagnosis depends upon the symptoms, and it will be best to consider these as they occur in (1) *Infants*, (2) *Older children*, and (3) *Adults*.

1. Adenoid Growth in very young infants are not so very uncommon, and the chief symptom for which advice is sought is snuffling at the nose. Although this symptom is most commonly due to the rhinitis of congenital syphilis, yet there is no doubt that a child may be born with "snuffles" entirely due to the presence of adenoid growths. Another symptom complained of is inability to take the breast or the bottle. This is due to the nasal obstruction present, which compels the child to take the lips away from the teat in order to breathe through the mouth. It has therefore to be fed with a spoon. Snoring is not such a common symptom in infants as it is in older children. Congenital laryngeal stridor is another condition which is sometimes due to adenoids. In infants the use of the post-nasal mirror is impossible, but the diagnosis can usually be made by a careful consideration of the symptoms of the patient.

2. In older children nasal obstruction forms a marked feature. The typical facies, with the open mouth, hanging lower jaw, thickened lower lip, and general look of stupidity is well known. The bridge of the nose is often widened from congestion of the soft parts, and the alæ nasi are frequently collapsed. Snoring during sleep, and a peculiar thickness in articulation are often noticed. But it must be borne in mind that some children do not keep the mouth open at night, and show the presence of adenoids only by want of development and by deformity of the thorax. Post-nasal catarrh is very common, and—especially when the hypertrophied masses lie in proximity to the Eustachian tubes—chronic catarrh of the middle ear and deafness may supervene. It is in these cases that the use of the post-nasal mirror is so important an aid in locating the growths round the Eustachian tubes. Very often this examination may be made when the child is first seen, but sometimes the nasopharynx is so sensitive that this is impossible. In these circumstances the writer always sends the child home for a week and gives the following prescription:—

R Potassii Bromidii	gr. v-x	Liquoris Potassii Arsenitis	$\mathfrak{M} iij$
(according to age)		Aquæ Menthæ Piperitæ	q.s. ad $\mathfrak{Z}ij$

Two teaspoonfuls to be taken in water three times a day after meals.

After this preparation the sensitiveness of the nasopharynx is so diminished that a satisfactory examination with the post-nasal mirror becomes possible.

Other aids in the diagnosis of adenoids in older children are the occurrence of granulations on the posterior wall of the pharynx below the soft palate, and the enlargement of the lymphatic glands along the posterior border of the sternomastoid muscle.

3. In adults who suffer from adenoids, advice is generally sought for three chief reasons :—

a. Chronic post-nasal catarrh often occurs in cases where the adenoids have been imperfectly removed in childhood and have subsequently recurred.

b. Deafness is also a frequent complaint. In adults it should be remembered that chronic otitis media, with indrawing of the membrana tympani, may have supervened, and that therefore a cautious prognosis should be given. Still, as the presence of adenoids tends to keep up the middle-ear catarrh, they should be removed.

c. Muffling of the voice, and a want of nasal resonance, are symptoms which become especially noticeable in singers. It has been said that singers should be operated upon as little as possible. When, however, it is remembered that the nasopharynx is a very important resonator of the voice, and is not a large space even when unobstructed by adenoid growths, it is clear that these should be removed and the space made as large as possible.

In considering the treatment of these cases, it has been urged that operation should be postponed until the general condition of the patient has been improved. Inasmuch as the adenoids are the exciting cause of the trouble, the writer believes that early operation is advisable, and that the improvement in the child's condition will be all the more rapid after the post-nasal growths have been removed. The respiratory exercises advocated by Arbuthnot Lane are valuable only *after* the nasal obstruction has been removed.

As regards operative treatment, the first consideration is the choice of the anæsthetic. On the Continent, tonsils and adenoids are removed without any anæsthetic at all, but owing to the intense nervous impression left upon sensitive children by this proceeding, the writer now always gives an anæsthetic. Of these, the best, in my opinion, are chloroform, a mixture of chloroform and ether, and open ether. In adults, gas and ether may be given, followed by chloroform. Gas alone, or gas and oxygen, does not give sufficient time, unless the operator be specially experienced and skilful. The writer has no experience of the use of chloride of ethyl. Whichever may be chosen, it should always be given by a skilled anæsthetist who acts in this capacity alone, and not as anæsthetist and general assistant combined.

The preparation of the patient for the operation is important. In very nervous subjects, the mixture of bromide of potassium and arsenic in doses suitable for the age of the patient should be given for a week beforehand. In adults the writer always gives 30 gr. of bromide of potassium in a large glass of water the night before the operation. An action of the bowels should be secured by aperients the morning before the operation, followed if necessary by an enema.

The operation is best performed in the early morning, when the stomach is empty. Care should be taken to see that the patient, if nervous, is not wakened too soon before the operation, and that no food, milk, or beef-tea is given in the early morning.

The head should be placed low at the edge of the table and on the right side. The writer prefers this position to that formerly advocated with the head hanging over the end of the table. The latter position leads to congestion of the veins of the neck, and consequently to greater hæmorrhage; and moreover, unless the head be firmly fixed by an assistant, it is difficult to remove the adenoid growth satisfactorily because of the mobility of the head.

Before the anæsthetic is given, a small gag should be placed between the teeth to allow of better breathing, since it should be remembered that nasal obstruction is already present. The anæsthetic should never reach the stage when the reflexes are completely lost, and before proceeding with the operation, the writer always inserts his finger, to make sure that the palatal reflex is present. It is of vital importance that the patient should be able to swallow the blood and to cough up any that accidentally enters the larynx.

There are two methods of removing adenoids which have to be described :

(1) *Operation with Löwenberg's forceps*, or with one of the modifications thereof ;
 (2) *Operation by means of the curette*. The writer no longer uses the curette, but relies entirely on the forceps. It is often difficult to remove the adenoids thoroughly by means of the curette, and very often only the central pad is removed. The growths tend to recur round Rosenmüller's fossæ unless completely removed from these situations, and, if left, the dangers of middle-ear complications are considerable. Moreover the writer has found that the patients experience far less pain and stiffness of the back of the neck after the operation when this is done with the forceps only, than when the curette is used. On the other hand, it is more difficult to learn to use the forceps than the curette, and the operation takes longer to perform ; but the extra time and skill required are well worth while, because it is only by use of the forceps that the adenoid growths can be completely and efficiently removed.

1. **Operation with Forceps.**—The patient having been anæsthetized, a Mason's or other suitable gag should be inserted in the left side of the mouth. In the case of adults it is always well to enquire beforehand if there are any teeth which have been crowned, so that they may be avoided, or the gag put on the other side. If no prop has been used there may be some difficulty in opening the mouth, as the patient should never be deeply under the anæsthetic. It can easily be overcome by inserting the forefinger between the jaws at the back of the last molar teeth, or by inserting the end of a tonsil guillotine and so forcing the teeth open.

The operator, standing on the right side of the patient, passes the forefinger of the left hand along the right side of the tongue over the tonsil, or below if the tonsils be large, until it reaches the posterior wall of the pharynx. He then turns it, with the dorsum of the hand on the tongue, up behind the posterior pillar of the fauces into the post-nasal space, which he examines thoroughly. Still keeping the finger behind the soft palate, and hooking it forward, he takes the largest pair of forceps that will fit the case, and passes them closed behind his finger. He then opens them as widely as possible, and keeping them closely pressed against the posterior wall, passes them up, guided by his finger, until as large a mass of growth as possible has been included. The blades are then closed, and with a slight twist and downward pull the mass is removed. The process is repeated until all the central mass is removed. By pressing on the mucous membrane below the forceps, it is easy to prevent its being removed along with the growth. He then takes a smaller pair of forceps, and turning them to either side, thoroughly clears out any growths that may be in Rosenmüller's fossa. It sometimes happens when the growths are in very great abundance, that pieces of them get pushed through into the nasal passages, and so cannot be gripped by the forceps. They can be pushed back again by passing a probe or pair of curved dressing forceps down the nose. In some cases the atlas projects forward so much that it prevents the forceps (or the curette) reaching the back wall. This difficulty can be easily overcome by using a pair of Quinlan's forceps, in which the cutting edges project backwards for about half an inch.

When tonsils are to be removed as well, they should be done after the adenoids. If the tonsils are removed last, sponging should not be required, and at any rate should always be done gently. On no account should the sponge be rammed into the back of the throat and turned round remorselessly, as if wiping out a glass lamp-chimney.

After the operation the patient should be turned over on to the right side, with the left hip and left shoulder brought well over, and the head brought to the edge of the table. Just before removing the gag the writer is in the habit of applying pure hazeline or Pond's extract by means of small pieces of sponge tightly gripped in the forceps and passed up into the post-nasal space and also

pressed on to the tonsils. It acts not merely as a local hæmostatic, but as an antiseptic and local anæsthetic.

As soon as the patient is out of the anæsthetic he should be instructed *not* to try to blow the nose for two or three days, as the cases of suppurative otitis media that sometimes occur are generally due to blood being forced into the Eustachian tubes at the end of the operation. In this connection it may be well to point out to the parents and the patient that the proper way to blow the nose in order to prevent injury to the ears is always to blow one nostril at a time.

2. Operation with Curette.—The operator should be provided with a guarded curette with prongs, and also with an unguarded one. The patient is in the same position as in the previous operation, although when nitrous oxide gas only is used some operators prefer to have the patient sitting up in a chair.

The curette is passed up behind the soft palate until it impinges on the vomer. It is pressed down on the growths, and with a rapid sweep the growths are cut through and brought out attached to the prongs. The unguarded curette is then passed up and turned first to the right and then to the left, care being taken not to injure the Eustachian tube, and is swept down and across to the opposite side. Even after the curette has been used by an efficient operator it is always well to remove by means of the forceps any little tags that may be left.

After-treatment.—The patient should be kept in bed for two or three days, and in the house for two days more, before being allowed out. He should also, if at all nervous, get a sleeping draught of bromide of potassium for two nights after the operation, and an aperient the second night. Should sickness persist for some time after the anæsthetic, it is a good plan to give 5 to 30 gr. of bicarbonate of sodium in a large tumbler of hot water. This is generally brought up again, and helps to get rid of the blood and mucus in the stomach. Milk should not be given for twelve hours, but weak tea and bread-and-butter, or beef-tea may safely be taken. Thirst is best controlled by giving alternate teaspoonfuls of very hot and cold water. The pain caused by the removal of tonsils is best relieved by a mouth-wash of hazeline or Pond's extract or very hot solution of carbolic acid (1-60), or, if need be, by blowing orthoform on to the cut surface.

When the operation has been primarily undertaken for deafness, it sometimes happens that the depletion of the mucous membrane of the posterior nares causes marked improvement in the hearing, which is noticed as soon as the patient wakes up. But treatment with Politzer's bag should be delayed for at least three weeks after the operation. Before employing it, an alkaline spray (not a douche) should be used for a week, in order to make certain that the post-nasal space is free from any discharge.

Breathing Exercises.—Owing to the nasal obstruction these patients have not been able to fill their lungs properly, their chests are not developed, and in some cases they have begun to be deformed. It is therefore of the utmost importance that breathing exercises, with special reference to nasal breathing, should be patiently and persistently carried out in a systematic manner until the patients have learned to breathe through the nose at all times.

In a great many cases the nares have become so narrowed that on trying to inspire quickly through the nostrils the *alæ nasi* are drawn in. When this happens the patient must be shown in a mirror what is being done, and made to practise expanding the nostrils during slow inspiration. From a long experience the writer has found the following exercises the most useful. They are all to be done standing up with the mouth firmly closed, so that both the inspired and expired air passes through the nose.

They are best done at bedtime and in the morning before dressing, as all tight clothing, such as corsets, braces, and tight waistcoats, renders them nugatory.

In fact it would be a good thing if boys learnt to wear their trousers suspended from the hips by means of a back-strap, and not wear braces at all.

a. The first set of exercises should be done against resistance. Three or four times a day the parent or nurse should stand in front of the patient and place the hands at the back of the lumbar region. The patient should then be asked to exhale deeply, so that the ribs go in. The patient's hands are then pressed strongly against the lower ribs. The patient should concentrate all his attention there, and try to push the hands outwards and backwards, and rather downwards than upwards, while taking in four short breaths through the nose.

The movement should be a backward one and confined to that part, and the chest as a whole should not be raised. After this has been accomplished, which may take from a week to a month, the hands should be placed higher up and a little more to the sides, and the exercises repeated. When this also has been successfully accomplished, the hands should be placed in the armpits, with the thumbs pressing strongly on the front of the chest. The patient should first try to separate the hands as far as possible laterally, and then endeavour to push the chest up against the thumbs. In order to prevent the muscles attached to the top of the ribs being brought into play or the shoulders being raised, the head should be allowed to hang forward.

When the patient is old enough he can do these exercises himself by making pressure with his own hands behind, and for the last exercise by putting a tape measure round the chest just above the nipple line and trying to exhale as much as possible, and then expand the chest laterally, and finally raise it. The difference between full inspiration and full expiration should be four to six inches.

b. The second exercise should be done standing in front of a looking-glass. The arms should be held out horizontally on a level with the shoulders, the palms facing the mirror. In this position, while taking in as full a breath as possible, the arms should be stretched away from the body to their utmost extent. While holding the breath, and keeping the arms fully extended and the head quite steady, facing the mirror, the arms and shoulders should be moved round until the right arm is straight in front and the left arm behind, and then swing back again. The exercise should be repeated about six times, bringing each arm alternately in front. The rotation, if possible, should take place in the spine, the head should not be moved at all, and the hips as little as possible.

c. In the third exercise the patient should stand with his back against the wall or a door. Both arms should then be raised above the head and stretched as high as possible, while inspiring slowly through the nose. Then, keeping the back of the hands and the elbows against the wall, the arms should be flexed until the hands are on a level with the shoulders. The breath should then be slowly expelled through the nose, the head allowed to fall forward, the shoulders be brought forward, and the chest compressed so as to get rid of all the air possible. This exercise should be repeated six times night and morning. (See also *JAWS, DEFORMITIES OF.*)

George C. Cathcart.

AEROPHAGIA.—(See *ERUCTION, NERVOUS.*)

AGORAPHOBIA, the dread of open spaces or the fear of crowded streets, and **Claustrophobia**, the dread of being shut up anywhere, should be treated by, as far as possible, correcting any errors of diet, giving suitable remedies for any gastritis that may be present, and diminishing the nervous excitability by such sedatives as bromide of potassium. Ewald speaks favourably of chloral in 10-gr. doses for agoraphobia. These symptoms are often associated with neurasthenia, and are benefited by rest, change of air, and all such means as improve the general health. (See also *NEURASTHENIA AND PSYCHONEUROSES.*)

Robert Saundby.

AIR-SWALLOWING.—(See *ERUCTION, NERVOUS.*)

ALÆ NASI, COLLAPSE OF.—In the less severe cases, when the patient has not lost all power of expanding the alæ, the best treatment is systematic exercise. The patient should be instructed to expand the nostrils for some minutes three or four times a day whilst standing in front of a mirror. A light resistance to the expansion should be made by gently compressing the nostrils with the finger and thumb. If these exercises are persisted in, great and permanent improvement usually results.

When, from atrophy of the muscles due to long disuse, the patient finds it

impossible to carry out these exercises, the nostril may be dilated by inserting a small roll of cotton-wool, about the size of a pea, into the most anterior part of the vestibule. The wool is invisible, and frequently gives complete relief to the nasal obstruction. Various dilators have been designed for the same purpose. These, and also the wool pads, generally produce so much discomfort that the patient refuses to wear them. If the obstruction causes the patient much distress, and cannot be overcome by the methods already mentioned, a small operation may be performed. A strip of mucous membrane, or of cartilage and mucous membrane, may be dissected up from each side of the septum and left attached by its upper extremity. It is then fixed in the anterior angle of the vestibule, so as permanently to expand the nostrils by acting in an exactly similar way to the pad of cotton-wool above described.

H. Lambert Lack.

ALBUMINURIA, Orthostatic, Cyclical, or Functional.—This affection, in which albumin is present in the urine whilst the patient is up and about, but disappears after rest in bed, may be regarded as one of the neuroses of childhood.

There is no evidence that the albuminuria is due to nephritis of any sort, nor that the condition ever leads to granular kidney or to any form of Bright's disease. Treatment by drugs, or by any means aiming at control of the albuminuria, is unsatisfactory, but calcium lactate has been found useful in some cases. Careful dieting, exercise, baths, and massage are generally inefficacious so far as the albuminuria is concerned, though valuable as means of improving general health.

Cyclical albuminuria is evidence of nervous instability, affecting chiefly the vasomotor system. It is best treated on general principles, which should include a simple, regular course of life, lived as much as possible in the open air, wholesome ordinary diet, and freedom from emotional excitement and overwork at school. The subjects tend to become valetudinarians and hypochondriacs, and therefore should not be treated as invalids.

Tonics, and sometimes sedatives, are necessary, if only to satisfy anxious parents that "something is being done," and the following prescriptions may be found useful:—

R Syrupi Calcii Lactophosphatis cum Ferro (N.F.)	3ss
Ex Aquâ 3ss three times a day after meals.	
R Calcii Lactatis	gr v-x
Syrupi Aurantii	3ss
Aquam Destillatam	
ad 3ij	
Three times a day.	

or if sedatives seem to be required:—

R Ammonii Bromidi	ãã gr iv	Sodii Hypophosphitis	gr ij-iv
Potassii Bromidi	¶ij	Aquam Chloroformi	
Liquoris Potassii Arsenitis	¶ij	Aquam Menthæ Piperitæ	ãã ad 3ss
3ij to 3iv three times a day.			

Leonard G. Guthrie.

ALCOHOLISM.—Of the various manifestations of the alcoholic habit which we are called upon to treat, some, such as acute alcoholic poisoning and delirium tremens, are acute; others, such as dipsomania and chronic alcoholism, are chronic. Alcoholic insanity, too, is to be borne in mind, but it does not fall within the scope of the present article.

Acute Alcoholic Poisoning (Alcoholic Coma).—This results from absorption of a quantity of alcohol so excessive as to produce not merely excitement or incoherence, but actual coma. When called to such a patient, proceed without delay to empty the stomach by washing it out through a soft stomach tube.

Emetics like apomorphine may produce dangerous depression of the heart, and are, therefore, inferior to gastric lavage with warm water. When the stomach has been completely emptied, before withdrawing the stomach tube, introduce half a pint of hot coffee and a dose of some saline aperient, such as 2 dr. of magnesium sulphate with 20 min. of dilute sulphuric acid in 2 oz. of peppermint water. If there be serious collapse, strychnine must be administered hypodermically, and artificial respiration may be called for if there be respiratory failure. Then allow the patient to sleep quietly, keeping him warmly wrapped up until he comes to himself.

Delirium Tremens.—Here, one's chief endeavours are directed towards calming the patient's excitement and procuring sleep. For these purposes he must be kept in a quiet room, with special nurses or attendants to watch him. A preliminary hot bath has an excellent sedative effect, and should be employed whenever available. Failing this, a cold pack is a good substitute, the patient being wrapped in a large sheet wrung out of cold water, and enveloped in several layers of thick blankets. He must be kept in bed, and fed with easily assimilable foods, such as hot beef-tea, milk, and strong soups. Mild cases sleep without hypnotic drugs, but in more severe ones it is necessary to give a hypnotic mixture, such as the following :—

R Potassii Bromidi	gr xxx	Tincturæ Hyoscyami	℥ xxx
Chloralis Hydratis	gr xx	Aquæ Menthæ Piperitæ	q.s. ad 3j

Half of this dose may be repeated in a couple of hours, if the first dose is insufficient.

In cases with wild motor excitement, $\frac{1}{100}$ gr. of hyoscyne hydrobromide may be administered hypodermically, and will generally calm the patient.

Mechanical restraint should be avoided as much as possible. A tactful female nurse usually succeeds in controlling the patient. She should, however, have the assistance of a strong male attendant, in case of emergencies. If the patient be violently excited and struggling to get out of bed, a good way to restrain him is by means of a folded sheet placed across his waist, between the blankets, including the patient and his bed, and tied firmly beneath the bed.

Alcohol should be avoided. If the heart fail, give strychnine hypodermically, and ammonium carbonate by the mouth. Careful examination of the chest should be made from day to day, lest pneumonia or other complication should arise.

When the patient has attained convalescence, he should be placed on a tonic mixture containing nux vomica, and it is well to send him off for a holiday, in the companionship of someone who will exercise over him a judicious moral influence.

Dipsomania.—Dipsomania is a recurrent paroxysmal impulse towards violent alcoholic excess. A characteristic of the disease is that the dipsomaniac has intervals, between his paroxysms, during which not only has he no particular desire for alcohol, but he may have even a distaste for it. Dipsomania is a congenital idiosyncrasy, and is not the mere result of habitual tipping.

Before the outbreak of each bout there is a premonitory stage of restlessness and irritability, during which the patient's character and disposition change—he sleeps badly, loses his appetite, and finally, after a few days, his craving for alcohol becoming irresistible, he drinks heavily and uncontrollably. The drunken bout may last a week, or longer. It then culminates in a sort of crisis, with gastric catarrh, vomiting, and prostration. The patient comes to himself, repentant and ashamed, and starts on another quiescent period, which culminates in due course in another attack of craving.

The treatment of true dipsomania varies according to the stage at which the patient comes under care. If the attack is already established, and he is

drinking hard, it can usually be cut short by giving hypodermically an emetic dose (gr. $\frac{1}{10}$) of apomorphine. This precipitates the gastric crisis, and produces acute vomiting, followed by profound sleep, generally lasting from three to eight hours. The patient wakes free from his craving. One may then administer smaller doses of apomorphine (gr. $\frac{1}{40}$ to gr. $\frac{3}{80}$) every three or four hours, for three or four doses, to maintain a mild hypnotic effect.

If the dipsomaniac be caught during the premonitory restless stage, when the alcoholic craving has commenced but he has not yet given way to drink, again apomorphine is of great value. An emetic dose is not necessary. All that is required is a small dose (gr. $\frac{1}{40}$ to gr. $\frac{3}{80}$) which produces faint nausea followed by several hours' sleep. When the patient wakes, this dose may be repeated.

Unfortunately we have no means of preventing the periodic recurrence of the craving, but must be content to watch for the premonitory stage and step in on each occasion with apomorphine.

During the non-drinking period treat the patient as a neuropathic subject, and by appropriate hygienic surroundings, physical, mental, and moral, maintain his general health in as high a state as possible. Hypnotic suggestion is often markedly beneficial. For successful hypnotic treatment the patient's co-operation is essential; he must be willing to be cured. Hypnotism, of course, can be successfully applied only during the inter-paroxysmal period. Deep hypnosis should be aimed at, and should be repeated every week for several weeks, and thereafter at longer intervals, so as to confirm the original suggestion. Not only must relief from the alcohol craving be suggested, but also a distaste for the drug. Total abstinence is the only safe rule for such patients. (See HYPNOTISM.)

Chronic Alcoholism.—For a reasonable prospect of success it is essential to have the patient removed from his home surroundings and placed in entirely new environment, under skilled supervision. For this purpose he should be induced to enter a special hospital or sanatorium, or, if this be unattainable, to place himself as a boarder with some medical man who will exercise benevolent control over him. Country surroundings are always best.

In such circumstances it is advisable in a severe case to commence without delay the special treatment by means of atropine and strychnine, originally advocated by McBride. The following is an outline of this treatment, as carried out at the Norwood Sanatorium:—

On admission a careful and complete physical examination of the patient is made. Unless there be some contra-indication, a brisk initial purge is given. On the following day the patient is put on a tonic mixture, containing liquoris cinchonæ concentratis ℥xxiv, liquoris gentianæ compositæ concentratis ℥viij, solutionis strychninæ nitratis (gr. iv ad ̄j) ℥j, solutionis atropinæ sulphatis (gr. j ad ̄j) ℥j, glycerini 3j, aquam ad ̄j. This is given five times daily, at intervals of three hours. On the second day, hypodermic injections of strychnine and atropine are added, and are administered three times a day, according to the appended plan.

Both drugs, it will be observed, are pushed until their full pharmacological effects are produced. We have a solution of strychnine nitrate (4 gr. to 1 oz.) and one of atropine sulphate (1 gr. to 1 oz.). Both these drugs are administered three times a day in progressively increasing doses. The dose of strychnine solution begins at 2 min. and increases by 1 min. every other day until the maximum (7 min.) is attained. The dose of atropine solution begins at 1 min. and is increased by 1 min. every other day up to the maximum of 6 min. In an average case the routine is as follows:—

First week.—Gradual increase to 5 min. of strychnine solution, and 4 min. of atropine solution.

Second week.—Continued increase to a maximum of 7 min. of strychnine solution, and 6 min. of atropine solution.

Third week.—Continuation of maximum doses of 7 min. of strychnine solution, and 6 min. of atropine solution.

Fourth week.—Reduction to 6 min. of strychnine solution, and 5 min. of atropine solution.

Fifth week.—Further reduction to 5 min. of strychnine solution, and 4 min. of atropine solution.

Sixth week.—Progressive reduction to 2 min. of strychnine solution, and 1 min. of atropine solution.

During the first week or two of treatment, i.e., until the effects of the atropine and strychnine injections are fully established, the patient confines his walks to the grounds of the sanatorium. Afterwards he can go out freely on parole, always returning at meal-times and at the hours for injections.

Such is the routine treatment in a case of moderate severity.

As to the withdrawal of alcohol in heavy drinkers, if this be done suddenly it is apt to produce insomnia and even delirium tremens or alcoholic epilepsy. It is therefore advisable to withdraw the alcohol gradually. In the case of a man who has been consuming say a bottle of whisky a day, we allow him three-quarters of a bottle the first day, two-thirds of a bottle the second day, half a bottle the third day, and on the three succeeding days 10 oz., 6 oz., and 2 oz. respectively. On the seventh day the patient gets no alcohol.

Open-air exercise without fatigue is to be recommended. Golf is particularly suitable as a pastime for such patients. A daily time-table of occupation should be laid down, and its performance insisted on. The diet must be generous, but easily assimilable. Daily warm baths are beneficial, and the bowels must be carefully regulated. Hours of meals must be regular, and also those of sleep.

All these measures obviously necessitate an amount of supervision which is difficult of attainment save in a household specially arranged for the purpose.

Whatever be the form of treatment adopted, the aim is essentially the same : to make the patient a permanent abstainer. Any attempt on the part of a former alcoholic patient to return to the intermediate class of "moderate" drinkers is almost certain to induce a relapse to his old excess. *Purves Stewart.*

ALOPECIA AREATA.—Since this disease tends, in young persons at least, to spontaneous recovery, it is not always easy to say how much of the benefit which may follow a particular line of treatment is due to it. At present stimulants and antiseptics are the most popular remedies, and some favour one, some another. The writer's preference is for lactic acid, which he uses in a lotion (5 to 10 per cent) with castor oil and spirit. After that come, in his estimation, sulphur and salicylic acid, 5 per cent of each in an ounce of lard ; chrysarobin, 5 per cent in equal parts of glycerin and chloroform (this must, of course, be used with great care, on account of the violent erythema it sets up on the face) ; and corrosive spirit, $\frac{1}{2}$ to 1 per cent.

Cases occasionally recover after the application of high-frequency currents, as they do after any or sometimes without any treatment ; *x* rays seem a somewhat paradoxical method of treatment, since they cause the fall of the healthy hair ; but in the exposure to the rays of the mercury vapour lamp, Kromayer seems to have found a method of treatment of real value in cases which fail to respond to less elaborate methods.

If the patient be anæmic, or if he show any other disturbance of general health, suitable internal treatment is indicated ; but the majority of cases of alopecia areata are otherwise quite well. (See also HAIR, DISEASES OF.)

It is very important that the treatment be continued until the hair is growing

vigorously on every one of the patches ; and it is well to bear in mind that the disease is not confined to the scalp, but attacks also the face, limbs, and trunk.

Norman Walker.

AMENORRHŒA.—Amenorrhœa may be apparent or real. Apparent amenorrhœa, or retention of menses, is due to the absence of a free exit for the menstrual discharge. This is generally the result of the presence of a septum at the vaginal orifice, but sometimes it is due to the partial or complete absence of the vagina. The treatment in such cases is, if practicable, to let out the retained fluid and maintain a free exit for subsequent discharges. This is easily done by means of a crucial incision in cases where the retention is caused by a septum, but where the vagina is completely absent this is impossible. A permanent passage can be maintained as such only if it is lined with skin or mucous membrane. In all cases of complete and many cases of partial absence of the vagina, menstruation must be put a stop to by the removal of the uterus, as it is impossible to provide for an exit for the recurring monthly discharges.

Real amenorrhœa may be congenital or acquired. In congenital cases it may be due to the absence or imperfect development of the uterus or ovaries, or of both. Such cases admit of no useful treatment. Occasionally real congenital amenorrhœa is met with in women whose pelvic organs appear on clinical examination to be normal. If it persists up to the twenty-fifth year it is almost invariably permanent.

Acquired amenorrhœa, apart from pregnancy, the period of lactation, and the menopause, is generally a symptom of some abnormal condition of health. In such circumstances the cause has to be sought for, and the general state of ill-health, of which the amenorrhœa is but one of the symptoms, must then be treated. Chlorosis is perhaps the most common disease to cause amenorrhœa. Rest, attention to the digestive organs, and subsequently the administration of iron, is the plan to be adopted. In simple amenorrhœa where there is no obvious anæmia, permanganate of potash in 2-gr. doses made up into a pill with kaolin and vaseline may be tried. Iron, however, generally does more good than any other drug.

Young women sometimes become rapidly very fat, and then often cease to menstruate. The cause of this state of affairs is not clearly understood. Massage, exercises, and a regulated diet may be tried. Lutein extract has been recommended in this condition.

W. J. Gow.

ANÆMIA.—This is a common accompaniment of many diseases (so-called "Secondary Anæmia")—in some cases so striking a feature that it appears in itself to constitute the disease (so-called "Primary Anæmia"). In either form the indications for treatment are the same, viz. :—

1. *Etiological.*—Removal, so far as possible, of the individual factors which, either singly or, as is more commonly the case, collectively, have co-operated to cause the anæmia.

2. *Remedial.*—Correction of the effects, e.g., loss of available iron, or diminished powers of blood formation, which the operation of the causes or the mere existence of the anæmia over a lengthened period of time has brought about.

The etiological distinction between secondary and primary anæmias—that while in the former the etiology is clear, in the latter it is unknown or indefinite—is, from the point of view of treatment, an artificial one. As a matter of experience, even in the latter group, indications for treatment, based on the existence of etiological factors, are not wanting, and require even more consideration than in the group of secondary anæmias, where they are so prominent that they do not need to be looked for.

The factors in the production of anæmia which afford indications for treatment may be grouped as follows :—

I. *Physiological*.—(1) Peculiarities in structure, functions, mode of formation, and destruction of blood ; (2) Age.

II. *Pathological*.—(3) Loss of blood—the result of traumatism or disease ; (4) Hygiene (air, light, and occupation) ; (5) Digestive and nutritional disturbances, with or without accompanying toxic effects ; (6) Infections, with their toxic effects.

I.—PHYSIOLOGICAL FACTORS.

1. **Peculiarities in the structure, nutritive, excretory, and circulatory functions, and sites and manner of formation and destruction, of the blood** constitute a most important factor, supplying the first and always supreme indication for treatment in all forms of anæmia, whatever be their nature. Its fluid structure, widespread distribution, and functions in nutrition and circulation expose the blood to the first brunt of injury from the many toxic influences, whether non-infective (e.g., digestive) or infective, capable of reaching it from the outside, especially through the oral, gastric, and intestinal tracts. The provisions made to protect the blood against such influences, viz., (a) the rich supply of *lymph cells* in the mucous membrane, especially of the digestive tract, constituting the first barrier ; (b) the *lymph glands*, most abundant in connection with organs supplied with mucous membranes, constituting the second barrier ; and (c)—in connection with the digestive tract—the existence of a third barrier of an altogether exceptional character, *the liver*, the excretory organ of the portal blood, one of whose great functions is essentially that of purifier of the blood—all these provisions are a precise measure of the degree of injury to which the blood is exposed, in virtue of its fluid structure, its sensitive character, and its widespread circulatory function.

The indication for treatment connected with this particular etiological consideration is exemplified every day in connection with every form of anæmia, namely, the supreme importance, as the first measure in treatment, of removing so far as is possible every source of possible trouble—functional, digestive, or infective—*however slight* it may apparently be, in connection with the whole alimentary tract ; and correcting by appropriate dietetic and medicinal measures any unhealthy conditions or impaired functions of the mass of active cells which not merely line this great tract, but also constitute the first great blood organ of the body. The beneficial effect of such measures is shown in everyday experience : (a) in connection with *chlorosis*, where the injurious influences are mainly of a non-infective (digestive) nature, and their effects are mainly functional, viz., impairment of functional activity ; (b) in all forms of “*secondary*” anæmia dependent on, or associated with, alimentary disturbances ; and perhaps most striking of all, (c) in the severest forms of anæmia often loosely and, according to the writer, altogether erroneously classed together under the general title “*pernicious*,” in which the injurious influences at work are always, according to his observations, of an infective nature (of a varying character afterwards to be referred to), operating with intensely aggravated effect both in impairing blood formation and increasing blood destruction, because they affect the blood in its most vulnerable part, viz., in the portal circulation.

2. **Age** is an important factor affecting the character and treatment of certain forms of anæmia. Youth is a period of relative anæmia, and this feature becomes specially marked at puberty, when, in addition to the ordinary and increasing demands of growth and adolescence, extra demands arise in connection with the onset of sexual functions and active work. Throughout this period the blood is relatively smaller in quantity, and poorer in hæmoglobin,

than at any other period of life ; whilst the body is also poorer in the amount of iron available for purposes of blood formation in the spleen, marrow, and other tissues. The deficiency in this constituent is the chief feature of the anæmia of youth and adolescence, and when this is accentuated by the periodic loss of blood by menstruation, the natural tendency to anæmia is greatly increased. It is with this period of life that the commonest form of anæmia—chlorosis—is associated.

The indications for treatment connected with age are : (a) to supply iron in greater quantity than is contained in the food, to meet the increased demands and compensate the periodic loss ; and (b) to recognize the unusual physical strain thrown upon so many young girls at this period of life by the often arduous duties which they at this time undertake.

The two chief indications in the treatment of chlorotic anæmia are, therefore, *iron* and *rest*. The former alone so often suffices that the importance of the latter is often overlooked or not sufficiently recognized. It is precisely this oversight that gives to severe cases of chlorosis the chronicity and apparent intractability to ordinary treatment which so often characterize them.

With advancing age—from thirty onwards—the natural tendency to chlorotic anæmia arising from want of stored iron in the body diminishes, and the greater is the likelihood that an anæmia of this type is due to other factors of a pathological character now to be considered.

II.—PATHOLOGICAL FACTORS.

3. Loss of Blood.—This may be due either (a) to injury to the vessel wall from trauma or ulceration (“*traumatic hæmorrhage*”) ; or (b) to injury to the vessel wall associated with and dependent upon disease of the blood (“*purpuric hæmorrhage*.”)

a. *Traumatic Hæmorrhage* is a common factor in anæmia, especially of secondary type. When associated, as it often is, with other factors, e.g., youth, digestive disturbances, etc., even the physiological loss of blood met with in menstruation may be a most potent cause of anæmia. It periodically deprives the body of an amount of iron equal to, or possibly larger than, the amount assimilated in the intervening period. The special intensity of the anæmia of young women—chlorosis—is in no small degree dependent upon such a periodic loss of iron, combined as it so often is with diminished intake of iron-containing foods.

Apart from such physiological variations, intermittent loss of blood is a potent factor in causing a severe anæmia of a chlorotic type at any time of life. As a practical point it may be said that, in adult life, the severer the anæmia, and the more chlorotic its type, the greater is the necessity for considering and excluding hæmorrhage as its possible cause. The best examples of such hæmorrhages are those met with in gastric ulcer, duodenal ulcer, and especially bleeding hæmorrhoids ; in women, menorrhagia or metrorrhagia associated with endometritis, or with polypi or fibroids of the uterus.

The indications for treatment of traumatic anæmia are connected in the first instance with the particular site and character of the lesion occasioning the hæmorrhage—gastric, duodenal, hæmorrhoidal, uterine, vesical—as the case may be ; or failing removal of the lesion itself, the checking of the hæmorrhage by suitable means.

As regards the effects of the hæmorrhage on the blood itself, the chief feature of this form of anæmia is the poverty in hæmoglobin, and the corresponding degree of hydræmia which results therefrom. The chief indications arising from these characters are the necessity for iron and arsenic as hæmatinics ; for rest ; for hypophosphites with strychnine as general tonics ; and for food as rich in iron as possible.

b. Purpuric Hæmorrhage, dependent on or associated with diminished coagulability of blood, is a factor in many cases of anæmia, especially of the graver (toxic) sort, and derives its importance in most cases, not from its own intensity, but from the toxic conditions with which it is associated.

In some cases, e.g., purpura hæmorrhagica, the hæmorrhages may be so numerous or extensive (e.g., epistaxis) as to be themselves the cause of a considerable degree of anæmia. But, as stated, this is exceptional. More usually the toxic features of the condition are the more prominent, and call for first attention. The anæmia is usually moderate in degree, even in purpura hæmorrhagica; it presents the characters of simple traumatic anæmia. In many mild cases there are hardly any demonstrable blood changes.

The indications for treatment that arise in connection with all purpuric conditions are, therefore, in a special degree etiological, viz., the detection (and removal, if possible) of every existing infective focus. In the writer's experience such foci are most commonly of a septic nature, and the anæmia associated with them belongs to that group which he has specially designated "Septic anæmia."

4. **Hygienic.**—Under this heading may be conveniently grouped the various factors connected with air, light, occupation, and surroundings which play so important a part both in producing certain forms of anæmia and still more in aggravating forms of anæmia arising from other causes.

Want of light, and bad air particularly, exercise a greater effect on the blood than on any other tissue of the body. The indications for treatment connected with this particular group of factors are obvious, i.e., a plentiful supply of fresh air, avoidance of the close atmospheres of crowded and overheated rooms, and—in particular cases—the selection, if possible, of other occupations.

As regards occupation, the amount of physical strain involved is no less important—and, as it happens, a far more common factor—than the actual character of the occupation. It is this circumstance which determines, to a degree insufficiently recognized, the peculiar incidence of anæmia in girls of the domestic-servant class. The young man at the age of sixteen or seventeen takes up an occupation which, however arduous, still permits him to go to and from his work in the open air, and leaves him many hours of freedom and rest from his work. The girl of the same age, entering domestic service, has duties placed upon her from early morning till late at night, involving continuous attention and physical strain, confining her continuously within doors, and depriving her—except at stated, and in most cases quite inadequately long, intervals of time—of any opportunities of getting fresh air. This strain and undue confinement girls undergo at the very period of life when, as already seen, they are especially subject to the influence of other anæmia-producing factors.

The indication for treatment arising out of these considerations is one of the most important in the whole treatment of anæmia generally, and especially of chlorosis—i.e., the absolute necessity of *rest*. In severe cases of chlorosis, three weeks' rest in bed will do more to effect improvement than any individual measure that may be adopted. In all special cases rest would greatly aid the operation of other measures.

5. **Digestive and Nutritional.**—This group of factors includes the manifold effects upon the blood of the numerous and various disturbances in digestion, assimilation, and alimentation connected with the amount and the character of the food taken; the activity of the gastric, intestinal, and hepatic functions; the efficiency of the various digestive processes dependent thereon; the presence of actual pathological conditions, such as catarrh and ulceration of the alimentary tract. It includes, moreover, the important influence exercised by the nervous system, through the mental emotions, upon the activity and efficiency of the

digestive process, determining as this does the likes and dislikes of particular classes of foods and drinks, the character of the appetite, the attention given to the regularity of meals, and the due regulation of other habits.

The effects upon the blood of the disturbances here had in view are of a definite kind. They affect chiefly the quantity and quality of the plasma and its constituents, and of the hæmoglobin. They are best exemplified in the anæmia connected with wasting diseases such as cancer, the ordinary forms of gastritis, enteritis, and diseases of the liver, and with chronic infective diseases such as tuberculosis. In no condition, perhaps, are they better exemplified than in chlorosis.

The degree of anæmia producible by disturbances in nutrition, pure and simple (apart from the operation of infective factors, presently to be considered), is comparatively slight. It affects chiefly the percentage of hæmoglobin, which is often reduced to 70, 60, 50, and even lower. The number of corpuscles, on the other hand, is comparatively slightly affected, percentages of 70, 80, 90, and even 100 being common in cancer—representing malignant disease—and in chlorosis—representing simple anæmia. In the latter condition, indeed, the number of cases in which the percentage of corpuscles is within normal limits is not much less than the number in which it is diminished. This fact is of importance from the point of view of treatment. When in such conditions the anæmia is of an exceptional degree, especially when the corpuscles are considerably reduced, the probability is that other than mere digestive and nutritive disturbances are co-operating factors—either those already considered, especially hæmorrhage, or still more commonly another great factor now to be considered, i.e., that of *infection*. Such infections operating within the alimentary tract are doubly effective in producing anæmia, for the reason already referred to; they not only affect the character and quantity of the food products absorbed, and disturb the processes of digestion; but, in addition, the toxins which they themselves produce act on the blood in that portion of the circulation where it is most vulnerable, viz., the gastric intestinal capillaries (portal circulation).

The indications for treatment connected with this particular factor of digestion are of importance. In all cases of anæmia, of whatever nature or degree, the first point is to attend to the digestive and intestinal functions, by promoting the appetite, by careful regulation of diet and habits, and by appropriate medicinal treatment.

6. Infective Factors play a great part in the production of anæmia, both in aggravating the effects arising from other causes, and still more in producing independent effects.

Acute general infections such as those of fevers, or chronic infective conditions such as tuberculosis, all produce anæmia of varying degrees; but the infections here in view are more especially those connected with the gastro-intestinal tract.

The infective factors operating within this tract may, according to the writer, be divided into three classes: (a) *Putrefactive*; (b) *Septic*; (c) *Specific*.

a. Putrefactive Infection.—Under this title may be included the effects produced by the action of those organisms responsible for the putrefactive and fermentative changes which normally occur within the intestinal tract. These include especially the *Bacillus coli*, and, in the case of children more particularly, the *Bacillus lactis aerogenes*. The intestinal disturbances in children, so commonly associated with the varying degrees of anæmia, are in many cases associated with, and probably due to, a large increase in the number of these two classes of organisms, to be found not only in the intestine, but also in the stomach, sometimes in almost pure culture; still more abundantly in the duodenum, and most numerously in the ileum.

In the case of adults, the effects of putrefactive change in the production of

anæmia are most commonly seen in connection with constipation. The anæmia is of the chlorotic type. Its chief feature is insufficiency of hæmoglobin.

b. Septic Infection.—The term “septic” here employed is confined, for convenience, to the two chief pyogenic infections, staphylococcus and streptococcus. By far the more important of the two is the streptococcal infection :

i. As a cause of “oral sepsis,” “septic gastritis,” and “septic enteritis.” The importance of septic infection as a great factor in the production of anæmia of every degree of severity cannot be too greatly emphasized. Its importance arises from the fact that it is so commonly overlooked—especially in connection with neglected septic lesions in the mouth (“oral sepsis”). As the writer has shown, this sepsis and its effects are not confined to the mouth, but extend to the stomach (“septic gastritis”), to the intestine (“septic enteritis”), and to the colon (“septic colitis”).

In the case of the stomach and intestine the effects are mainly functional, and arise from varying degrees of catarrh. When severe and long-lasting they may lead to deeper-seated changes in the mucosa, e.g., sub-acute and chronic gastritis, enteritis, and colitis.

ii. As a cause of “septic anæmia.” The effects of “oral sepsis” are, however, much more severe and widespread, and affect the blood directly. For the sepsis connected with foul gingivitis, especially when associated with deposits of tartar and suppurative inflammation round necrosed roots, is a sepsis in direct contact with open wounds, the absorption from which must be considerable ; although it may be slight in amount at any one time, its cumulative effect upon the blood, over many years, must be great.

So important are these effects that the writer has been led to designate by the special name of “*septic anæmia*” the form of bloodlessness arising from this cause.

In its slighter manifestations this anæmia is exceedingly common as a factor aggravating other forms, and if it be present, its oversight gives to many apparently simple anæmias their unusual severity and their apparent intractability to ordinary measures of treatment. In its severer forms it can give rise to a degree of anæmia equalling that of pernicious Addisonian anæmia, with which it has hitherto been generally grouped. It is, however, sharply distinguishable from it by its pathological, hæmatological, and clinical features, and is essentially due to deficiency of blood-formation usual in the chlorotic type.

iii. In relation to pernicious Addisonian anæmia. Septic infection plays an important part in the development of this disease, although however severe it may be it is unable of itself to produce it. It is, however, a potent *antecedent* condition, creating the unhealthy conditions in the stomach and intestine which favour the contraction of the specific (hæmolytic) infection responsible for the disease, and which favour its *continuance* after its contraction. The typical mode of development of this disease is an antecedent history of oral, gastric, or intestinal trouble *associated with sepsis* for some years previous to the onset of the disease, and without any special sign of anæmia. This is more or less suddenly followed by a rapidly developing and *hæmolytic* anæmia (with lemon colour, sometimes by jaundice) out of all proportion to the severity of any symptoms or lesions connected with the alimentary tract.

c. Specific Infections.—In addition to the foregoing factors, specific infections are from time to time present in the intestinal tract, which either alone or—as is more frequently the case—aided by the above-mentioned infective factors, powerfully affect the blood, and produce anæmia of varying degree. The most severe form of anæmia, i.e., pernicious Addisonian anæmia, owes its origin, according to the writer's observations, to such a special infection, characterized by an intense hæmolytic action on the blood, by a distinctive group of clinical features, and by a definite mode of origin.

In a proportion of cases—as large as 20 to 25 per cent—the contraction of this hæmolytic infection can be traced to exposure to the influence of severe drain poisons.

TYPES OF ANÆMIA.

After the foregoing consideration of the etiological factors concerned in the production of anæmia, the treatment to be adopted may conveniently be considered in connection with three forms of anæmia representing the chief types met with :—

1. *Chlorosis*—often termed a primary form of anæmia, but in reality secondary—the purest form of all anæmias, owing its origin to the operation of a number of factors, slight in themselves, but of a non-infective character.

2. “*Septic Anæmia*”—a form of anæmia hitherto not sufficiently recognized, but recently differentiated by the writer, owing its origin to the existence of sepsis in connection with the oral, gastric, and intestinal tract—one of the commonest forms of anæmia, frequently complicating and greatly intensifying all other kinds, sometimes so intense that in itself it constitutes one of the severest forms of anæmia—resembling in its intensity the severest of all, Addison’s anæmia (pernicious anæmia), and hitherto generally grouped with this form, but differing from it in its pathology, in the character of its blood changes, and in its prognosis.

3. “*Addison’s Anæmia*.”—“*Pernicious infective anæmia*”—a form of anæmia of infective origin of specific nature, in which sepsis is a most important antecedent and concomitant factor, but has grafted on to it an intense hæmolytic which marks it off sharply from septic anæmia; and characterized throughout by a mode of onset, a characteristic group of clinical features, a clinical course, and a prognosis (resistance to treatment) sharply distinguishing it from septic anæmia.

CHLOROSIS.

The first point in the treatment of this condition is the recognition of the various factors, usually slight in degree, concerned in its production. These are connected :—

1. With the characters of the blood in youth, especially from fifteen to twenty-two, when this form of anæmia is most prevalent; i.e., the blood at this period has 10 per cent fewer corpuscles, 8 to 10 per cent less hæmoglobin, 5 per cent more water, and is smaller in quantity than at any other period of life.

2. With growth and development at the period of puberty.

3. With occupation—throwing additional strain on the body, and at the same time usually associated with more confinement, less air and light, and more physical strain, than in the period of life prior to puberty.

4. With disturbances in digestion, diminished appetite, dyspepsia, and constipation—affecting not only the general nutrition, but also in a special degree the amount of iron ingested. Whereas a normal dietary contains daily $\frac{1}{11}$ to $\frac{1}{8}$ gr. iron, the dietary of three chlorotic girls was found to contain only $\frac{1}{50}$ to $\frac{1}{20}$ gr.

5. With periodic loss of blood at this period, slight in itself, but important when combined with diminished intake of iron, and greatly aggravating the chlorosis when, instead of the natural and protective process of amenorrhœa, the opposite condition of menorrhagia is present.

To these more constant and important factors may be added the disturbances connected with psychical and mental emotions, associated in a special degree with this period of life. The effects of these are aggravated by one circumstance quite peculiar to this period of life, and to this condition, i.e., that girls consider

pallor to be attractive rather than otherwise; and in the classes in which chlorosis is most prevalent they not infrequently from pure choice adopt a dietary such as rice (the poorest of all in iron constituents), tea, and milk, and avoid or have even a repulsion to meat, the one food which contains the iron of which they stand in need.

If to these be added the factor which undoubtedly exists in certain families more than in others, i.e., the natural predisposition to pallor, we have before us a brief summary of the physiological and pathological factors which, operating together, amply suffice to explain the origin of this anæmia, and place it not only in the group of secondary anæmias, but also among the purest and most typical forms of secondary anæmia.

To the above factors of non-infective nature there may, however, be added others which are infective, notably sepsis; originating especially in oral sepsis, and associated with gastric and intestinal sepsis; and independently causing varying degrees, slight or severe, of septic anæmia. The combination of chlorosis, pure and simple, with this septic anæmia is, in the writer's experience, a very common one, and gives to many cases of chlorosis their severe and chronic character, and their resistance to the ordinary measures of treatment to which, in the absence of this septic anæmia, they would otherwise respond.

The measures, then, to be adopted in treating chlorosis are the following:—

1. *Digestive*.—The correction of the gastric and intestinal disturbances (dyspepsia and constipation) which are so frequently associated with the condition.

2. *Dietetic*.—The substitution of foods richer in iron for those which the patient has been taking.

3. *Medicinal*.—(a) The supply of additional iron in the form of preparations which experience has shown to be the least disturbing to digestion, the most assimilable, and the least constipating; and (b) The use of other tonics, notably of arsenic, hypophosphites, and strychnine, which experience shows also exercise a beneficial influence, not only directly on the blood-forming powers (arsenic), but also on the nervous tone of the whole intestinal tract (phosphites and strychnine).

4. *Hygienic*.—The correction, so far as is possible, of those ways of living which place too great a physical strain upon the general bodily powers at this period of life, and deprive the patient of the air and light which are as necessary to the formation of hæmoglobin as they are to the formation of the colouring matter of plants. (See *PATHOLOGICAL FACTORS*, *supra*.)

5. *Climatic and Balneological*.—Measures supplementary to the foregoing in severe cases resisting the ordinary and generally successful measures of treatment.

Digestive Treatment.—It is essential in cases of chlorosis to correct any digestive disturbances, and to remove the constipation, as a first step in the treatment. As the condition is usually one of chronic dyspepsia, not infrequently of gastric catarrh, and in some cases of actual ulceration of the stomach (gastric ulcer), these can be best removed by stomachic sedatives, especially soda and bismuth preparations. The following are some of the preparations with combinations which will be found useful for this purpose:—

To be taken at night.

Even when digestive intestinal disturbances appear to be absent, it is always well to commence the treatment of chlorosis by measures directed especially towards this tract. Unless this is done, it will often be found that the iron which we desire to administer disagrees, and its administration has to be stopped until the stomach and intestine have been restored to a healthier condition by the use of the foregoing preparations.

Dietetic Treatment.—The appetite is in many cases so poor that the diet indicated is one often described as light and easily assimilable. It is usually held to include more especially such articles as milk, soups, and farinaceous foods in the form of milk puddings, with fish and chicken. It will be seen, however, from the following table that this class of food does not contain the amount of iron of which this condition stands in special need. This is particularly true of farinaceous food, especially of rice, which is actually the poorest

in iron, and the one most frequently used (if not actually abused, if, as is stated, some of the domestic class, in which chlorosis is notoriously most prevalent, make a practice of eating dry rice for the very purpose of producing a pale complexion).

The chief point as regards diet is the necessity of increasing the amount of meat, which contains two to eight times more iron than is present in such an article as rice; three or four times the amount contained in flour; twice or thrice the amount contained in potatoes; two to seven times more than the amount contained in milk. The following table gives the percentage of iron in the various classes of food most commonly in use* :—

LIST OF FOODS WITH THEIR IRON CONTENTS (*Bunge*).

100 Grams of	Mgrams of Iron.	100 Grams of	Mgrams of Iron.
Rice contains ..	1.8	Strawberries ..	8.9
Rye	4.9	Cabbage	3.9
Wheat	5.3	Spinach	35.9
Oats	13.1	Cows' milk ..	2.3
Corn	3.6	Human milk ..	2.7
Potatoes	2 to 6.4	Beef	4.8 to 16.6
Peas	6.6	Eggs	5.7
Beans	7.4 to 8.3	Fish	1.5 to 84.2
Lentils	8.3 to 9.5	Veal	2.7
Apples	13.2		

Food.—The diet in anæmia should, therefore, to a considerable extent, consist of animal food—preferably underdone—and in severe cases, especially in children, great advantage can be obtained by the administration in the raw form, pounded up, and given either alone or with various meat extracts to mask its appearance and taste.

Patients should be encouraged to take—in however small a quantity—chopped or scraped beef, mutton, chicken, eggs, bread and butter, milk; amongst vegetables, lettuce; amongst fruits, oranges, stewed apples, and prunes. Pastries and sweets, for which chlorotics often have special relish, are harmful in most cases, and should be avoided.

The chief difficulty with most anæmic patients is the loss of appetite and the enfeebled digestion. The best treatment for this is to send the patients to bed. With rest in bed, even a feeble digestion can supply the wants of the body, with a little to spare for improvement. So long as they continue to go about and do their work, such patients make no progress, whatever the character of the food or however much iron they take. Digestion may be assisted by the administration of hydrochloric acid and pepsin, or malt with each meal. Food should be taken in smaller amounts and at intervals of four hours. Liquids should be taken sparingly, especially with food.

Medicinal Treatment.—The most important measure is the administration of iron, continued for eight to ten weeks at least; then intermitted for two or three weeks, and afterwards taken in smaller quantity, and continued for several months. The object to be aimed at is not merely to restore the blood to its normal percentage of hæmoglobin, but to afford time for the body to lay up some reserve of iron in its blood-forming tissues.

The particular form of iron preparation is immaterial, provided only that it does not disturb the digestion, and that it agrees with the patient. The inorganic preparations in ordinary use are perfectly efficient, and give the best results. The choice of the particular preparation is guided largely by the condition of digestion and of the stomach.

Reduced iron, ferrous carbonate of iron in one form or other, or one of the

* Bunge here refers to 100 grams of dry substance; not as they appear as food.—ED.

scale preparations, e.g., citrate of iron and ammonia, is the least irritant; protochlorides and sulphates are distinctly more irritating, and the ferric salts still more so.

Reduced iron is tasteless, but repellent in appearance, and is apt to cause unpleasant eructations. It may be given in 2 to 5 gr. doses, in rice, capsule, or chocolate form, or in form of a powder to be taken between two slices of bread. *Perchloride of iron* gives very good results in anæmia from convalescence, but is apt to cause disturbance of digestion. *Citrate of iron and ammonia* gives good results, especially when it is necessary to continue iron for a long time. It is especially suitable for children on account of its pleasant taste. The best results are, however, got with *ferrous carbonate*, especially when freshly prepared, as in its well-known combination of ferrous sulphate with potassium carbonate, in Bland's pill, or pil. ferri carbonatis, or ferri carbonas saccharatus (3 to 5 gr.)—a good chalybeate very free from astringency—also contained in mistura ferri composita. In many cases the iron may, with advantage, be administered along with laxatives, such as aloes or saline cathartics, as in some of the combinations already given.

The following are some of the combinations which have been found most useful :—

Arsenic is a valuable blood tonic in many cases of anæmia, either alone or in the form of liquor potassii arsenitis (3 to 5 min.), or in combination with iron, either as arsenious acid in doses of $\frac{1}{50}$ gr., or as arseniate of soda.

Iron Waters are useful in various forms of anæmia, especially in those due to acute illness or actual loss of blood, also in cases of long-standing chlorosis.

The waters to be preferred are those containing bicarbonate of iron with free carbonic acid. In cases where there is dyspepsia, with intestinal catarrh or a tendency to hepatic disorder, their use is better preceded or accompanied by that of muriated or sulphated alkaline waters, or of aperient drugs. They are contra-indicated in feverish conditions, and in severe disturbances of the digestive organs.

With regard to such chalybeate springs, the best known are those of Spa in Belgium, Schwalbach, and St. Moritz. Spa waters contain a considerable amount of bicarbonate of iron and a large amount of free carbonic acid. The latter makes them pleasant to most people. Schwalbach waters are strong, fairly pure chalybeate, containing an excess of free carbonic acid with scarcely a trace of sulphuretted hydrogen. At St. Moritz, Switzerland, also, the springs are chalybeate, rich in carbonic acid, and very pleasant to the taste. Compared with those of Schwalbach they are relatively poor in iron, but owing to the climatic conditions they are in many cases more effective than stronger springs at lower situations. On the other hand, the high altitude (5,800 ft.) is not suitable for nervous or excitable patients, and is distinctly disadvantageous, according to the writer's experience, in severe cases of any form of anæmia, especially chlorosis. The worst case of chlorosis he has seen—the only one which ever gave him immediate cause for anxiety—he found at a high altitude in Switzerland. The rarefied atmosphere, combined with the great deficiency in hæmoglobin, caused severe dyspnoëic distress such as he had never seen in any chlorotic patient. This distress had begun and been attended by fainting attacks half an hour from the time when the patient began to ascend from the level of the valley (1000 ft. altitude) to the four or five thousand feet at which she was found.

Of English chalybeate springs, Tunbridge Wells is one of the oldest (1606) and best known. The waters do not contain free carbonic acid. Cheltenham and Melksham have muriated, sulphated waters. The tonic effect of such waters is greatly aided by the use of the chalybeate baths. These act chiefly by virtue of the large amount of carbonic acid present and the stimulating tonic effect which the bubbles of this gas exert on the nerve-endings of the skin.

Balneological.—The benefit derived from courses of such waters is greatly enhanced by—if not largely due to—the change of scene, the enforced rest, the stricter dietetic régime, the stimulating and tonic effects of baths—especially those saturated with free carbonic acid, as at Schwalbach and Homburg—which many of the foreign spas provide.

The foregoing general principles for the treatment of chlorosis are applicable to all cases of non-infective anæmia. The principles applicable to the treatment of "Infective Anæmias" are of a different and more directly etiological and preventive character.

SEPTIC ANÆMIA.

The form of anæmia to which the writer has given the above title is, according to his observations, at once one of the commonest and one of the least recognized types. It frequently complicates other forms of anæmia, e.g., chlorosis, malignant disease, Bright's disease, pernicious Addisonian anæmia, leukæmia, the intestinal infective anæmias of children, purpura, etc., giving them an intensity out of proportion to their ostensible cause. In certain cases it is so severe that it can occasion an anæmia resembling in degree, and hitherto mistaken for, pernicious (Addisonian) anæmia, but differing from the latter in essential pathological respects, most notably in the absence of the

hæmolysis and of the glossitic changes which characterize Addisonian anæmia. In some cases the septic absorption is connected with leucorrhœal discharges, but in the great majority the septic lesions are in the alimentary tract.

In many cases the trouble is connected with chronic suppurative lesions in the nasal sinuses. The maxillary antrum is the sinus most often affected, less commonly the ethmoidal and frontal sinuses, and rarest of all the sphenoidal sinuses. It frequently happens that more than one of these cavities are discharging simultaneously, several drachms of fœtid pus being secreted and swallowed daily for many years. The patient becomes so accustomed to this discharge that in most cases he makes no mention of it—he has always had it, and does not connect it with the general loss of strength and ill-health which have gradually developed.

Still more commonly the seat of septic trouble is the mouth itself—the existence of “oral sepsis,” manifested by deep-seated alveolar suppuration in connection with decayed roots, tartar, unclean plates and stoppings, pyorrhœa alveolaris, and lesions of gums connected with these conditions.

The important point to be noted is that the degree of anæmia is often so marked that none of the usual evidences (redness and pain) of inflammation are present, and lesions of an intensely septic character are on this account frequently overlooked.

TREATMENT.—The prime indication is the discovery and removal of the sepsis underlying the condition. The oral antiseptic treatment to be employed includes not merely the use of mouth-washes (these exercise a very superficial effect on the oral sepsis present in such cases), but the more direct treatment of the septic lesions around each affected root. In many slighter cases this can be done most effectively by swabbing the affected roots and gums, after the removal of any tartar present, with 1–40 carbolic lotion, and in cases of oral sepsis this measure should never be omitted, even in those which subsequently require the services of the dentist. Wherever possible, diseased roots should be removed, particular care being taken, by careful antiseptic precautions both *prior* and subsequent to the operation, to prevent any subsequent complications.

In most cases the effects of the long-existing oral sepsis have extended to the stomach and intestines, and have created unhealthy conditions of the mucosa (“septic gastritis” and “septic enteritis”), which require to be dealt with by appropriate gastric and intestinal sedatives, laxatives, and tonics. The most useful drugs are those with disinfectant properties, especially bismuth salicylate (10–15 gr. thrice daily before food), perchloride of mercury (30 min. to 1 dr. doses of the liquor 1–1,000), salicylic acid, or salol. The response to such measures is immediate—*after the removal of the sepsis of the mouth*.

After removal of the sepsis, recovery from the anæmia can be promoted by the usual hæmatinic drugs—iron and arsenic, or hypophosphites—and by the other dietetic, medicinal, and hygienic measures applicable to all forms of anæmia (see ANÆMIA). But it is astonishing how very little such drugs are required, and how rapid is the recovery after the sepsis is effectually removed in such cases.

ADDISONIAN OR PERNICIOUS ANÆMIA.

General Considerations.—The treatment of this severe disease is greatly influenced by the view taken of its pathology. Next to the profound degree of the anæmia, the two most prominent features presented by the blood are: (1) The extraordinarily severe and pernicious character of the blood destruction—hæmolysis; (2) The no less striking powers of recovery. Both these features are more marked than in any other form of anæmia. It is not uncommon to find a patient's blood reduced from the normal standard of 90 or 100 per

cent to 20 or 30 per cent in the course of a few weeks, accompanied by all the clinical evidences of intense blood destruction, viz., high colour of urine, urobilinuria, lemon colour, biliousness, and occasionally jaundice. No less striking is the rapid recovery of the blood when the hæmolytic is arrested. The percentage of corpuscles and hæmoglobin often rises from 20 or 30 per cent up to 80 or 90 per cent within a month or two, in some cases in the course of three to four weeks.

This remarkable power of recovery is a natural feature of the disease, and its most hopeful one. From the point of view of treatment, however, it is often misleading, since the particular treatment in use at the time of its occurrence is wrongly credited with having produced it—with having cured the disease. It misleads, moreover, in another way, with unfortunate results. For so remarkable is the recovery, that doubt is cast, both by the doctor and the patient, on the accuracy of the original diagnosis. The patient feels and looks so well that he resumes his ordinary occupations and habits of life, and gives up all treatment. There follows, in a period varying from six to nine months, the usual relapse, fatal in about three-fourths of the cases. In a certain number, however, recovery again takes place, although more slowly, and less complete in character; the patient remains well for another period of three to six months, when a second relapse occurs. A certain number recover even from this, and the writer's experience satisfies him that under suitable treatment this number is steadily increasing.

General Management and Diet.—

During acute attacks.—The symptoms in severe cases are those of an extremely severe acute febrile disease, added to those of severest anæmia. The characteristic symptoms are the fever, often reaching 102°, 103°, or even 104° F., sickness, vomiting, or diarrhœa, very severe general disturbance, headache, drowsiness, sometimes semi-unconsciousness. These are accompanied by a marked lemon-colour—almost jaundiced—appearance.

When these severer symptoms subside they continue in a milder and modified form, sometimes for two or three months at a stretch; varying slightly at intervals of two to three weeks, and accompanied by a slight irregular fever, ranging from subnormal in the morning to 99° or 100° F. in the evening.

During this period the general treatment to be adopted should be that for a case of typhoid fever. The patient should be strictly confined to bed, and fed at intervals of every four hours with food in small quantity. The basis of such food should be milk—either alone, or peptonized, or half-peptonized—milk puddings, junket with cream, beef tea or various forms of meat juices, bread and milk, tea and milk or coffee and milk, raw beef juice, pounded chicken or meat, and bone marrow when tolerated. Experience shows that no absolute rules of diet can be laid down suitable for all cases. Individual patients display the most variable likes and dislikes for particular foods; and show, moreover, a most remarkable tolerance for foods which would appear unsuitable. One of the chief objects in treatment is to ascertain for each case the particular diet which he can tolerate with the least gastric discomfort.

Such discomfort, often marked by retching and sickness, forms one of the most distressing features of the disease. The sickness usually occurs in the early morning—on awaking—and before food is taken. In severe cases, in the later stages of the disease, it may occur at any time, and often does so two or three times a day over many weeks. It is entirely independent of the character of the food or medicine given.

This fact is an important one; for the sickness is often referred quite erroneously, both by patient and doctor, to the food or medicine, and this leads to unnecessary changes. The sickness is due, partly to infective inflammatory

lesions of the mucosa of the stomach which tend of themselves to heal up after a time, and partly to toxæmic influences. The gastric symptoms may best be relieved by an occasional mustard-leaf or poultice over the stomach, and by administration by the mouth of sedatives—especially bismuth—with soda, or hydrocyanic acid, or nepoche. When very severe, all food given should be peptonized.

The toxæmic character of this vomiting is best evidenced by the remarkably sudden way it subsides when the acute character of the disease passes off, as it often characteristically does, with great suddenness. The patient, who has been lying at the point of death, oedematous all over, delirious, vomiting nearly everything he takes, suddenly takes a turn for the better—gets a “crisis.” He wakes up conscious, calls for food and drink, takes everything without discomfort, and makes a rapid recovery.

Medicinal Treatment.—All tonics—hypophosphites, malt, strychnine—capable of affecting the blood beneficially, may from time to time be found of use in the treatment of this anæmia in suitable cases. The only one, however, which has any special effect is *arsenic*. Its use is attended in most cases—for a time at least—with marked benefit. Until recently, when the antiseptic and antitoxic treatment presently to be described was introduced, it has been almost the only remedy capable of producing benefit in any considerable proportion of cases. It is best given in the form of Fowler’s solution (liquor potassii arsenitis) in doses of two to three minims thrice daily after food. It may also be given subcutaneously in the form of arsenate of iron (Martindale), or in the form of arsenical waters.

Many observers recommend that the larger the dose, and the more rapidly it is pushed, the better. The writer does not share this view. On the contrary, it is his experience that cases which respond to arsenic do equally well with smaller doses. Large doses have this great disadvantage, that they induce an intolerance of the drug; and this militates greatly against its use in the subsequent relapses which invariably occur. The object to be aimed at is, then, to keep the patient on small doses of arsenic (2–5 min.) as long as improvement continues; to continue the arsenic in 2–3 min. doses for periods of months subsequent to apparent recovery. By careful regulation of dose in this way, the writer has found it possible, with occasional intermissions, to keep a patient on arsenic for a period of several years without the slightest disturbance.

Bone Marrow.—The other remedy from which benefit may from time to time be got is ox-bone marrow, administered either fresh on toast, or in the form of tabloids. First introduced by Sir T. Fraser, of Edinburgh, it has been found useful by various observers, who speak strongly in its favour and recommend that it should be persevered in and its administration pushed to a much greater extent than has hitherto been done. In many cases it cannot be tolerated.

Antiseptic Treatment.—This treatment aims at:—

1. The complete removal by local antiseptic measures in the case of the mouth, and by use of internal antiseptics in the case of the stomach and intestine, of the oral, gastric, and intestinal sepsis associated with the disease.

2. Special local antiseptic treatment of the infective glossitis present, supplemented by measures for raising the antitoxic power of the blood by a serum treatment.

The line of treatment based on the above considerations is, then, the following, in their order of importance:—(1) *Oral, Gastric, and Intestinal Antisepsis*, supplemented by (2) *Antistreptococcic Serum Treatment*.

1. **ANTISEPSIS.**—The result of the writer’s observations has been to locate the specific hæmolytic infection underlying the disease definitely to the tongue, stomach, and intestine, and to trace its source to drain infection.

The contraction of this infection is favoured and facilitated by long-standing oral and gastric sepsis.

a. Oral Antisepsis.—It is chiefly important in all cases of *commencing* anæmia to direct special attention to the removal of any sepsis, *however slight*, connected with the tongue, diseased teeth, or gums. Far more than ordinary care should be taken with regard to the condition of the teeth, not only by direct local antiseptic measures, but also, whenever practicable, by the removal of old stumps, black teeth, or teeth showing commencing carionecrosis. These precautionary measures are necessary, irrespective of any statements made by the patient as to the degree of discomfort such roots and bad teeth are causing, or of the absence of any inflammation around them. As a matter of fact indeed, however severe the degree of oral sepsis may be, it is rare to have attention drawn by the patient to his mouth, or to have any complaint made by him.

Discomfort and pain in the teeth are the result of local inflammatory reaction—periostitis and gingivitis. They indicate relatively healthy conditions, inasmuch as they denote that the local tissues still have the power to react more or less actively to septic infection. There is a stage, however, in severe anæmic conditions, as indeed in other forms of infections, when local reaction is absent, or at least insignificant, at the very time when the general septic effects are most marked. (See SEPTIC ANÆMIA.)

b. Gastric Antisepsis.—The chief seat of the infection is in most cases the stomach; and the first effect of the infection is an infective catarrh, followed later by deeper-seated changes of the nature of glandular atrophy, and gastritis, evidenced by intermittent vomiting of inflammatory streptococcal exudation.

The indications here are to remove or combat this catarrh, either by *washing out the stomach*, suggested on the view that many of the symptoms of the disease were due to abnormal fermentation of food products within the stomach, or still better, by *administering local antiseptics* to diminish or destroy the infection underlying the catarrh.

Later observations have demonstrated the intensely infective (streptococcal) nature of the catarrh, and the progressive character of the gastric changes which it produces.

In all cases the use of local gastric antiseptics should be steadily persisted in. The one that has proved successful in certain cases against ordinary infective gastritis has been salicylic acid. This drug was selected on general grounds as the antiseptic which appeared to be at once the most powerful and the least harmful, and the result was eminently satisfactory. Improvement was noticeable at once, and salivation and sickness ceased from about the fourth or fifth day, with remarkable resulting improvement in the blood condition in two weeks' time. Other observers have since reported favourable results with this drug.

Other useful antiseptics are the various bismuth preparations (especially bismuth salicylate), perchloride of mercury, charcoal, carbolic acid.

c. Intestinal Antisepsis.—In one group of cases the intestinal symptoms predominate, or occur from time to time. In this group the best disinfectants are perchloride of mercury, calomel, or small doses of grey powder or blue pill.

2. SERUM TREATMENT.—It is obvious, however, that if once the infection gets firmly rooted in the mucosa, mere local antiseptic treatment—however much it may benefit by diminishing or removing catarrh, and thus arresting the disease temporarily—may fail to arrest it permanently, even when aided, as when possible it ought to be, by the use of arsenic and by dietetic measures; and experience proves only too fully that such is the case. The only indication for treatment, then, is to combat the action of the poison on the blood after its

absorption. The writer has therefore given a sustained and systematic trial to a serum treatment based on the results above stated.

Antistreptococcic serum was selected, inasmuch as observations point to streptococcal organisms as always being concerned in the infection. Its use is based, not on any hypothetical considerations as to the nature of the anæmia, but on the series of observations which step by step served to trace the anæmia back to an infection arising in connection with the alimentary canal.

The first case treated on the lines then recommended, viz., oral and intestinal antiseptics combined with antistreptococcic serum, was that recorded by Dr. William Elder, of Leith (April, 1900). The case was a severe one of pernicious anæmia. The treatment was oral and intestinal antiseptics, with injection of antistreptococcic serum. None of the usual remedies for anæmia were given. The result was that in forty-five days after the commencement of the treatment, the blood condition rose from 18 per cent of corpuscles with 24 per cent of hæmoglobin to 96 per cent of corpuscles and 104 per cent of hæmoglobin. A month later "he reported himself as feeling fit and well, and looked in very good health." In all, no fewer than eighteen injections were given in the course of six weeks, without any ill-effects, either local or general.

The first systematic trial made of this treatment by the writer was in a case which was very typical in its mode of onset, the character of its gastric symptoms, its urinary changes, its nervous symptoms, and its oral symptoms, and it was in a comparatively early stage.

The blood condition was 30 per cent of corpuscles and 35 per cent of hæmoglobin. The treatment was milk diet, oral and intestinal antiseptics, ammonium carbonate and tincture of digitalis as a cardiac tonic, and injection of antistreptococcic serum.

In all, four injections of the latter were given—viz., 10 c.c. on the 9th and 13th July, followed later by two injections of 5 c.c. Before treatment was commenced (July 7, 1900) the blood condition had further deteriorated, the red corpuscles being reduced to 27 per cent.

Between July 9, when he got the first injection, and August 1 (i.e., three weeks), the corpuscles had risen from 27 per cent to 65 per cent, and the hæmoglobin from 35 per cent to 75 per cent; and one notable feature of the blood at this time was the marked leucocytosis—leucocytes 17,000 per c.mm. (instead of the normal 5,000 to 7,000). He received a fourth and last injection (5 c.c.) on August 1.

The patient continued to improve for the next ten days, although his actual blood condition showed some relapse; and he then went to the country (Aug. 16). The treatment was as before—namely, strict oral and intestinal antiseptics, with, in addition, 1 oz. of the syrup of the hypophosphites thrice daily as a tonic. Arsenic was still withheld. He returned in six weeks' time (Sept. 26) greatly improved in looks; and his blood showed red corpuscles 3,200,000 (64 per cent), and hæmoglobin 80 per cent.

He was now given liquor potassii arsenitis in 3-min. doses thrice daily, increased to 5 min. three weeks later. The result was that when he reported himself on Nov. 8, 1900, his blood showed: red corpuscles 4,040,000 (80 per cent), hæmoglobin 90 per cent, and leucocytes 7,500 per c.mm.; his weight was 11 st. 3 lb. (157 lb.), an increase from the time he came under observation of nearly 2 st. (24 lb.); and his gastric and intestinal functions were in all respects normal. He still retained the feeling of numbness in his fingers, although this had recently greatly lessened.

He was kept under continuous observation and strictest antiseptic treatment the whole time. For the last seven years he has remained to all appearances a stout healthy man: but severe relapses in the blood have from time to time occurred. Even these have now ceased: and his blood has remained at 100 per cent of corpuscles and 120 per cent of hæmoglobin—weight 12 st. 7 lb.

In this case the diagnosis was made and the treatment begun early in the course of the disease, two years after the first onset of the anæmic symptoms, but within a few months of the first serious breakdown. In other words, the patient was seen before the recuperative powers of the blood had been exhausted time after time by repeated exacerbations of the disease. This is one of the few cases which the writer has been able to treat from the earliest stages onwards, since his usual experience is to see such patients only in the later stages of their illness, after their first or second relapse. In a recent case similarly treated the effect of serum treatment was even more striking. The blood, which had remained about 20 per cent for over two months, rose to over 60 per cent in the course of seven days, and to 80 per cent in three weeks; the opsonic power

against *Streptococcus longus* rising from 0·65 to 0·85. The patient went out, apparently a healthy woman, in three weeks' time.

In certain cases the serum caused a distinct general reaction, lasting usually for forty-eight or sixty-four hours. Whether its presence was connected with the character of the disease, or of the special serum used, it is impossible to state. But in view of its possible occurrence, it is, I consider, advisable to begin with small doses (5 c.c.).

As has been said, the object of the serum treatment is not to replace the line of treatment by arsenic as hitherto employed—and up to a certain point successfully—nor is it to replace the new line of treatment by combined oral and intestinal antiseptics which the writer has recommended. *A far greater importance is to be attached to the latter than to arsenical treatment, inasmuch as it aims at the removal of the combined infections— hæmolytic and septic—which underlie the disease.*

It is certain that the disease cannot be permanently checked by the use of arsenic alone. But that may possibly be due to the fact that up till now—the infective nature of the disease and the importance of sepsis not having been recognized—the infective lesions have been left undisturbed, and hence the patient, cured once by arsenic, has remained continuously exposed to fresh outbreaks of his infective trouble.

The prime object of the combined oral and intestinal antiseptic treatment is to remove infective lesions and septic conditions which favour their persistence. If this succeeds, there may be no necessity for further treatment other than by arsenic.

If both together fail to arrest the disease, the serum treatment is the one which appears to hold out most prospect of benefit, and the cases recorded certainly denote that it has markedly therapeutic properties.

William Hunter.

ANÆMIA, SPLENIC.—(See SPLENIC ANÆMIA.)

ANÆMIA, TROPICAL.

Climatic.—Minor degrees of anæmia are common, especially in women and children, and are to a great extent due to the sedentary life rendered necessary by the avoidance of sun and consequent restrictions on open-air life. Moderate and regular exercise, at suitable times and always short of fatigue, is the best remedy. Iron is useless; constipation must be dealt with.

Secondary.—Malaria, sprue, kala azar, trypanosomiasis, and many other acute and chronic diseases lead to a secondary anæmia. Removal of the primary cause is essential; arsenic, after the causes (malarial, etc.) are treated, is of more value than iron, but the combination of the two is often beneficial. Intramuscular injections of arseniate of iron are often of great value. Solutions, such as Squire's liq. ferri arsenatis solubilis, in 10 to 20 min. doses, containing 2·5 per cent of the salt, may be given every alternate day.

Ankylostomes are the cause of a most severe form of anæmia. They are common in the natives, less so amongst Europeans. Removal of the worms is essential. Large doses of anthelmintics are necessary. Oil of male fern is sometimes used, but more often thymol. The patient should be kept on a low diet for the previous day, and a brisk saline aperient given. Thymol, 10, 15, 20, or even 30 gr., should be given in cachet or capsules at daybreak after fasting for twelve hours, and the dose repeated twice at intervals of one hour, and followed by a full dose of ol. ricini, or, better, by a saline aperient, as the oil may dissolve the thymol. The stools, when strained, will reveal the presence of the worms. Occasionally symptoms of cerebral disturbance or syncope follow the administration of thymol. This is more often the case if alcohol or

oils in any form are taken shortly before or after, as then the absorption of thymol is much increased on account of the solubility of thymol in alcohol or oil.

An efficient substitute for thymol is eucalyptus oil and chloroform, given in castor oil (ol. eucalyptus 30–35 min., chloroform 40–45 min., ol. ricini 10 dr.): (eucalyptol in the same doses is used by many). This should be divided into two doses, and they should be given the first thing in the morning, after the same preliminary treatment as with thymol, with an hour's interval between the doses. Frequently the treatment has to be repeated several times, as some worms still remain. β -naphthol, in 15-gr. doses three times repeated at intervals of one hour, is also effective.

The proof of complete expulsion of the worms is the absence of ova from the stools two or three weeks after the treatment. If ova are still found, the treatment must be repeated. After the complete expulsion, beyond a generous diet with careful attention to the digestive functions, little is required. Iron is useful in the later stages of recovery, but is not advisable at first.

C. W. Daniels.

ANÆSTHETICS, Administration of.

I.—PREPARATION AND EXAMINATION OF THE PATIENT.

Preparation.—Whenever preparation of the patient is possible, it should be arranged that no solid food should have been taken for at least four hours, and that the bowels should have been emptied by a suitable purgative, followed when necessary by a simple enema. This is not possible in some emergency cases; and in giving an anæsthetic to a patient who has not been prepared, it is important that a careful watch should be kept for the first signs of vomiting, the head turned to the side, and special care taken that the vomit is cleared out of the mouth, so that none may be sucked back into the respiratory passages.

For the administration of ethyl chloride and nitrous oxide no strict preparation is necessary; but a better anæsthesia will be obtained if no food has been taken for two hours, and the bladder should be empty.

When a patient in a feeble condition is about to undergo a serious operation, a hypodermic injection of strychnine (gr. $\frac{1}{30}$) may be given—though it is better to give small doses during the previous day or two—or a rectal injection containing half an ounce of brandy. Before a long administration of “open” ether an injection of atropine (gr. $\frac{1}{100}$) should be given, to prevent the secretion of much mucus; and with it many anæsthetists give morphia (gr. $\frac{1}{4}$ to $\frac{1}{2}$), or scopolamine (gr. $\frac{1}{100}$), especially before abdominal operations. Less ether is then required, relaxation of the abdominal muscles is more easily obtained, and there is often less sickness on recovery.

Examination.—In examining a patient before the administration we must not be surprised to find the pulse very rapid, as this is often produced by dread of the proceedings. A systolic murmur at the apex is not of great importance, provided there are no symptoms of want of compensation, such as breathlessness, or signs of back-pressure, as œdema in the feet, and moist sounds at the bases of the lungs. In these patients much care will be required in the choice and administration of the anæsthetic, and no closed inhaler should be used.

Particular attention should be paid to the way in which the patient breathes, and when the breathing is entirely through the mouth a dental prop should be placed between the teeth to ensure this air-way remaining patent throughout the administration, and it is advantageous to use a prop between the teeth even when a patient seems to breathe well through the nose. A cough is often due to pharyngeal irritation, especially in smokers, but the lungs should be examined for signs of bronchitis.

Artificial teeth must be removed unless very firmly fixed, and loose teeth should be noticed, as these may give trouble when it is necessary to insert a gag.

II.—ADMINISTRATION OF GENERAL ANÆSTHETICS.

Nitrous Oxide, or "gas" as it is more generally called, is now almost always given by means of Hewitt's apparatus. A suitable face-piece is selected, and attached to the stop-cock, while the bag is half filled with gas. The face-piece is now carefully applied to the patient's face, and a few breaths of air are allowed, to see that the valves of the apparatus are working properly and that the face-piece is fitting accurately. The lower slot of the stop-cock is now closed, so that gas is breathed instead of air, and the signs of anæsthesia will soon be noticed. First the colour of the face gradually becomes darker, the pupils dilate, twitching movements known as "jactitations" are noticed, generally beginning in the fingers or the smaller muscles of the face, and the peculiar "stertor" associated with nitrous oxide is heard. If the face-piece is removed as soon as the first twitchings are noticed, a period of anæsthesia lasting on the average about thirty seconds will be obtained.

By interspersing a few breaths of air with the nitrous oxide, which may easily be done by opening the lower slot of the stop-cock, a longer and quieter anæsthesia may be obtained, lasting on the average from forty to fifty seconds. When this is done, the patient should not become cyanosed, and no marked jactitation or stertor should be observed. When air is given with gas the best sign of anæsthesia is the gradual increase in the depth and freedom of the respirations, with slight snoring, which is quite different from the loud stertor mentioned above. In giving air with gas in this way a little practice is necessary before the best results are obtained, and it should be remembered that children and anæmic girls require more air than robust men.

An equally satisfactory anæsthesia may be obtained by giving pure oxygen with the gas in the Hewitt's special gas and oxygen apparatus.

When gas is given for a short operation, say one lasting for five minutes, it is obvious that air must be allowed, either by opening the lower slot, or by removing the face-piece from time to time. The great advantages of gas for short operations consist in its safety, the absence of any unpleasant smell or taste, the small amount of preparation of the patient which is required, and the rapid recovery, which is usually accompanied by no unpleasant after-effect. It is most frequently used in the single-dose method for the extraction of teeth and other dental operations; but when given continuously for a few minutes, short operations which would otherwise be painful, and which do not demand a great depth of anæsthesia, may easily be performed. Among these are the opening and draining of abscesses, removal of nails, moving stiff joints, etc. But without considerable experience it is not easy to give gas well for more than a few minutes, and when longer anæsthesia is required, it is wiser to change to ether.

Ethyl Chloride.—This anæsthetic has been extensively used by some anæsthetists during the last few years, and many forms of apparatus have been devised for its administration. All that is really required is an ordinary face-piece, such as is used for giving gas or ether, attached to the bag of a Clover's inhaler. The ethyl chloride is sprayed into the bag, and the face-piece applied. It is a good plan to make a small hole in the metal angle-piece of the bag, just large enough to admit the nozzle of the ethyl chloride spray, and this hole may be closed with a spring, or even a wooden peg. If this is done the administration will be more pleasant for a nervous patient, as a few breaths may be allowed into the bag before any ethyl chloride is sprayed into it, and when regular breathing is established the drug may be added as required. For a single-dose anæsthesia,

such as is required for a dental operation, 5 c.c. should be enough for a man, 3 c.c. for a woman, and 2 or 3 c.c. for a child.

Anæsthesia is obtained with almost startling rapidity, and a child who is crying loudly with fright and struggling vigorously, after taking two or three deep breaths will be found to be profoundly anæsthetized, with dilated pupils, and no corneal reflex. The great rapidity and ease with which anæsthesia is obtained is at once an advantage to the careful administrator and a grave source of danger to one who is careless.

The anæsthesia obtained by a single dose may easily be made to last a minute, or even longer, which is more than can be obtained with certainty with nitrous oxide, unless administered by the nasal method. The anæsthesia, too, is profound at first, and is sometimes followed by a period of analgesia, in which teeth may be extracted while the patient is conscious of what is being done but yet does not suffer pain. When ethyl chloride is given for the removal of tonsils or adenoids, especially when the patient is sitting up, it is dangerous to allow the anæsthesia to become too deep, or blood may enter the larynx and laryngotomy be immediately required to restore the patient's breathing, and there is often a serious fall in the blood pressure.

The great advantages of ethyl chloride consist in its portability, the simplicity of the apparatus required for its administration, and the ease with which anæsthesia can be obtained; but it is certainly not nearly so safe as nitrous oxide, and during the last few years many fatal cases have attended its use. It is also more likely to be followed by unpleasant after-effects, such as headache and vomiting, which are unusual after gas.

In nearly all the forms of apparatus for the administration of ethyl chloride the principle of administration is the "closed" one, that is to say, rebreathing into a bag takes place. Some anæsthetists consider that rebreathing is to be blamed for the headache, etc., and now spray the ethyl chloride on to the sponge of a Rendle's inhaler, such as is used for the administration of A.C.E. In this way more of the anæsthetic is used, as it is very volatile, but the results are said to be satisfactory, especially in the case of children.

Ether.—Ether may be administered by the "closed" or "open" method. In the "closed" method the patient breathes into a bag attached to some form of apparatus by which the strength of the ether vapour is regulated. Clover's inhaler, with a large bore as suggested by Hewitt, is one of the best forms, or the simpler inhaler designed by the writer. In giving ether by one of the inhalers the face-piece is selected and fixed to the inhaler, and a measureful (2 oz.) of ether is poured into the latter. The anæsthetist should then blow through the apparatus to remove the ether vapour which is in the central tube. The bag is then attached and the inhaler applied to the patient's face during expiration only, so that the bag may be distended with his breath. When the bag is about one-half or two-thirds full the inhaler is kept applied to the face, and a few breaths are allowed before the indicator is turned. The actual administration of ether is then begun by slowly turning the indicator, and so allowing more and more of the respired air to pass through the ether chamber. The comfort of the patient, and the ease with which anæsthesia is produced, depend in great measure on the very slow and gradual way in which the indicator is moved, especially during the first two or three minutes. By giving too strong a dose at first the patient will be worried, and will either cough, or hold his breath and struggle; but if the administration is begun slowly and gradually, anæsthesia may generally be obtained in a few minutes without any trouble or discomfort. For vigorous men it is sometimes necessary to turn the indicator to "Full"; but for women it is not necessary to go beyond $2\frac{1}{2}$ or 3, and with children $1\frac{1}{2}$ is quite sufficient. In all cases the strength of the vapour should

be reduced as soon as anæsthesia is obtained. When full anæsthesia has been obtained the bag may be removed, thus practically converting the administration into an "open" one. When this is done the indicator should be advanced, and if the anæsthesia becomes too light at any time the bag may be re-applied for two or three minutes.

The administration of ether is made much more pleasant by giving some nitrous oxide first. This may be easily done by filling a bag full of gas, and applying it to the ether inhaler in place of the usual small bag. The patient is allowed a few breaths of air through the valves as when gas is given alone, and the lower slot is then closed, so that the patient now breathes gas through the valves. When half the gas has been used in this way, the upper slot is closed, and rebreathing into the bag takes place without the action of any valves. The indicator is now turned rather more quickly than when ether is given alone, and when anæsthesia is obtained the gas bag may be removed, and the smaller bag substituted. In the writer's gas and ether apparatus the gas bag contains no valves, but what is known as a three-way stop-cock. Through this the patient first takes a few breaths of air, and then, by turning the handle, rebreathing into the bag containing the gas at once takes place. This way of giving gas with a gradually increased proportion of ether is known as Clover's method.

Another method, known as Braine's, consists in placing the patient fully under the influence of nitrous oxide, that is, giving it till jactitation is noticed, and then giving a full dose of ether at once. This may be done either with a Clover inhaler with the indicator at 3 or "Full," or with an Ormsby inhaler. This method requires much practice.

With "gas and ether," anæsthesia may with safety be obtained more quickly than with "open" ether or chloroform and its mixtures, and a rapid loss of consciousness is an advantage in the case of very nervous patients.

For the administration of ether by the "open" method, sixteen layers of ordinary surgical gauze are stretched on a Schimmelbusch frame, or one of its modified forms, and ether is gradually dropped on the gauze from a bottle.

A piece of gauze should be twisted into a rope and placed between the mask and the face, covering the eyes, but leaving the mouth and nose quite free; or a pad of Gamgee wool may be used, with a hole cut in it for the mouth and nose. By these means the free access of air is prevented, and the patient breathes through the gauze on the mask, and becomes anæsthetized more rapidly.

If no pad is used and a free supply of air is allowed, as is the case during an administration of chloroform, the method is more strictly an "open" one; but the strength of the ether vapour then obtained is so low that it will generally be insufficient, except for patients in a feeble condition, or for the closing stages of a prolonged operation. Ether is dropped on the mask slowly at first, but in increasing quantities, though the gauze should never be saturated. The amount required varies considerably, depending on the vigour of the patient, the temperature of the room, etc. Anæsthesia is obtained more slowly than with the "closed" method, and larger quantities of ether are used, but a satisfactory anæsthesia is often more easily obtained by this "open" method, especially by those who have not had much experience of the other. A preliminary injection of atropine (gr. $\frac{1}{100}$), about half an hour before the administration, is useful in preventing an excessive secretion of mucus and saliva; and for abdominal operations, when the surgeon does not object, morphia may be added. The administration is made more pleasant if it is begun with a mixture of chloroform and ether, such as the A.C.E. mixture; but ether alone should be given after the first two or three minutes. "Open" ether has been much used lately as a routine anæsthetic, both on account of the simplicity of the apparatus required, and the relative safety of the method.

Ether may also be given in a semi-open manner by using a Rendle's inhaler, giving a mixture (see **Mixtures**) till anæsthesia has been obtained, and then pouring pure ether on the sponge, when required, instead of more mixture. The writer has found this specially suitable for women and children, and much less ether escapes into the room.

The great advantage of ether over chloroform lies in its safety, which is of course of the first importance; but it is not so pleasant to take, it sometimes produces a considerable amount of secretion of mucus and saliva, and its after-effects, such as vomiting and the unpleasant taste it leaves, are more marked than those of chloroform.

Chloroform is frequently given from a piece of lint; but as with this there is some chance of burning the skin, the method suggested by Lister is preferable. It consists in drawing the corner of a towel through a safety pin till a mask is formed reaching from the chin to the root of the nose. The best form of mask is Skinner's, which is a piece of flannel stretched over a light metal frame. With this there is less risk of the patient's face being burned, there is a freer admixture of air, and there is no possibility of the breathing being in any way obstructed, as sometimes happens when a piece of lint is carelessly allowed to fall over the mouth.

The administration of chloroform by either of these means is very simple, and is called the "open" method. A few minims are dropped on the lint, and the mask is held some inches above the patient's face, so that the first inspirations may contain a very weak proportion of the drug. The chloroform is added drop by drop as required, and the mask gradually brought nearer to the face.

As with ether, too strong a vapour will cause holding of the breath, coughing, or struggling, and much care should be exercised to prevent these. The respiration should be most carefully watched, and should be kept as free and as regular as possible. When the breath is held, the mask must be removed from the face to prevent too large a dose being taken with the next inspiration. The lips should be rubbed with a towel to stimulate the breathing, and when this is satisfactory the mask may gradually be restored to its former position, and more chloroform given. When the mask has been held too close to the face, or when the flannel has been saturated with the drug, the first deep inspiration after holding the breath has allowed patients to absorb a fatal dose. The part of the mask which lies over the mouth and nose may be kept moist with the drug, but liquid chloroform must not be allowed to drop from the edges of the frame, or the skin will be burnt.

Before any administration of chloroform the patient should be carefully prepared; all clothes, etc., should be loosened, and the patient should be in the recumbent position. Though chloroform causes no congestion in the air-passages, it is most important that a free air-way should be maintained.

The careless administration of chloroform has resulted in many deaths, and several forms of regulating apparatus have now been devised in which it is not possible for the patient to inspire more than a definite proportion of chloroform vapour. The Vernon Harcourt inhaler is probably the most accurate. With it a definite chloroform vapour of from 0.2 to 2 per cent can be given, and by a further contrivance the strength can be increased to over 3 per cent. That the patient shall really receive these percentages it is essential that the face-piece should fit perfectly accurately, and even then it is not always possible to obtain the deep anæsthesia which is sometimes required; but it is surprising to find how easily a sufficiently deep anæsthesia may be maintained in many cases with a very small percentage.

Chloroform may also be given by means of a face-piece made of lint or flannel attached to the tube of a Junker's inhaler. A fairly constant proportion

of chloroform vapour can be presented to the patient, the strength varying with the rate and the vigour of the pumping. It may be raised to 4 per cent, which Lister calculated is all that is required; but if at any time a stronger vapour is needed, a few drops of chloroform may be added on the face-piece.

When an operation is being performed in the mouth, Junker's inhaler, with a mouth or nasal tube, is the only apparatus by which we are enabled to maintain anæsthesia, unless the surgeon perform laryngotomy, in which case the chloroform is given through the wound. The latter is the most satisfactory method for very extensive operations, as it allows of the pharynx being tightly packed with sponges and so prevents the entrance of blood into the larynx and trachea.

The advantages of chloroform as an anæsthetic consist in the ease with which it can be administered without any complicated apparatus, and its not unpleasant smell. It produces a quieter anæsthesia without the congestion of the air-passages and the unpleasant secretion of mucus and saliva which are so common with ether, while at the same time it more easily obtains the full relaxation of muscles which is required for some of the extensive modern operations in the abdominal cavity. Against these advantages, it cannot be denied that it is a far more dangerous drug than ether, and this should always be considered in choosing an anæsthetic, especially as with "open" ether, preceded by morphia and atropine, an anæsthesia sufficiently deep can in most cases be obtained with much less risk to the patient.

Mixtures.—Many attempts have been made to combine the good effects of chloroform and ether by giving them together in mixtures of different proportions. The best is the A.C.E. mixture, consisting of one part of absolute alcohol, two parts of chloroform, and three parts of ether. It should be kept in a dark cupboard, in stoppered bottles containing four ounces.

Mixtures are often made at the time of the administration, and in this case the alcohol may be omitted, and a mixture of two parts of chloroform to three of ether, or of one part of chloroform to two of ether, may be made by measuring the liquids, pouring them into a bottle, and gently shaking them before using.

Mixtures are especially suitable for children and for old and weakly patients. When very little anæsthetic is required, they may be given on a Skinner's mask; but when the patient requires more, a Rendle's inhaler will be found very suitable. In the case of an adult, a drachm of the mixture should be poured on the sponge, and the inhaler placed a few inches from the face. It is gradually brought nearer till it rests lightly against the face. After two, three, or four minutes, another drachm of the mixture should be poured on the sponge, and if necessary another dose at a similar interval; but it should be remembered that this anæsthetic is practically a diluted form of chloroform, and that more time should be allowed for anæsthesia to be obtained. If it be given too freely, or the air-supply to the patient be cut off too completely, the symptoms of chloroform poisoning will result from any mixture of which it forms a part.

III.—THE ANÆSTHETIC STATE.

Whatever may be the drug employed to produce anæsthesia, and however complicated may be the apparatus, the points to be noticed in the condition of the patient are the same.

Respiration.—It is most important that the respiration should be very carefully watched during the whole of the administration. While the patient is still conscious, there will be many variations both in depth and rhythm; but when consciousness has been abolished, it should become free and regular, and every effort must be made to keep it so. The great cause of obstructed breathing is the tongue, which tends to fall back and rest against the pharyngeal wall.

To obviate this, the head should be well turned to one side, preferably to the right, unless the operation is being performed on the right side of the head, neck, or thorax, when it should of course be turned to the left. Pressure should be made with one or more fingers of the left hand behind the left angle of the patient's jaw, while the fingers of the right hand hook the chin forwards and upwards. By these means the tongue is carried forward, and at the same time the loose folds of mucous membrane which lie above the opening of the larynx are stretched, and so prevented from causing obstruction.

In some patients it will be found that the lower teeth become locked behind the upper ones, so that, however much force be exerted, the jaw will not move forward. In these cases an attempt should be made to open the mouth and fix the lower teeth in front of the upper ones; but if this is not possible, a small prop should be placed between the teeth. It is especially important that a clear air-way should be maintained through the mouth when the breathing through the nose is obstructed, and some administrators use a small prop between the teeth as a matter of routine. It should have a string or piece of tape attached to it to prevent its being swallowed.

When the operator requires the head to be kept in the middle line, it may be found impossible to prevent the tongue from falling back, even when firm pressure is exercised behind both angles of the jaw. In this event direct traction on the tongue must be employed. The ordinary forceps bruise the tongue so much that they may cause considerable pain, lasting for two or three days; when the tongue must be pulled forward for some time, it is better to use a simple ligature passed through its substance.

Respiration may be obstructed also by pressure on some part of the respiratory tract, as by an enlarged thyroid gland pressing on the trachea, or by fluid in the pleural or abdominal cavities. When this is the case the anæsthesia should be kept as light as possible till the pressure is relieved.

The breath is often "held" when the anæsthesia is allowed to become too light, and vomiting is imminent; respiration will then be improved by rubbing the lips and then giving more of the anæsthetic. If vomiting occurs, the head should be turned to the side, and all vomited matter carefully removed from the mouth before any more anæsthetic is given.

When too much air is given, a condition of "false anæsthesia" may be obtained, in which the patient breathes extremely quietly, and is apparently ready for the operation, but shows vigorous movements when the incision is made. This condition is most commonly noticed in infants; it is more likely to occur when the patient has been anæsthetized for some minutes before the surgeon is quite ready to begin.

Pulse.—While a patient is being rendered unconscious, the pulse will vary considerably through the influence of excitement; but when anæsthesia has been established, it should become regular, of good volume, and of moderate rate. Though it is not necessary to observe the pulse as continuously as the respiration, it should be carefully watched, as it will generally give the first indication of the shock which a severe operation causes a patient, by becoming faster and smaller. It should be remembered that the pulse may be made fast and small by pushing ether unduly and so over-stimulating the circulation.

The Colour of the patient will be best observed in the lips and ears, and should never be allowed to become at all dusky. If cyanosis occurs, more care must be taken to keep the air-way clear, and to remove the inhaler for longer intervals.

Corneal Reflex.—The reflex movement of the eyelids produced by touching the sensitive cornea is one of the most useful guides to the anæsthetist. As a general rule this reflex should be abolished for the skin incision, and then in many operations it may be allowed to return. For instance, the anæsthesia

will generally be sufficiently deep while the reflex is present in operations on the limbs, and even in many abdominal operations, when the surgeon is working on parts that are not very sensitive. Thus, for a long resection of intestine the corneal reflex may be abolished while the skin incision is made and the parts are placed in position; but while the intestines are being sewn the reflex may be allowed to return, care of course being taken that no other signs of light anæsthesia, such as straining and vomiting, are allowed. However light the anæsthesia which may be sufficient for the greater part of these operations, it is generally found necessary to deepen it while the abdominal wall is being manipulated at the close of the operation and the sutures are being inserted, as otherwise the operation may be ruined by vomiting at this critical moment.

For some operations the corneal reflex should always be retained; among these are the removal of tonsils, adenoids, and the thyroid gland, operations on the brain, pleura, etc. But in some patients vomiting sets in so soon after the return of the reflex that it is necessary to keep it absent on this account, though otherwise the operation in itself does not demand deep anæsthesia. This will be more noticeable in nervous patients, who secrete and swallow large quantities of saliva while they are waiting for the operation to begin, and in those who have been badly prepared. In testing the corneal reflex, care must be taken that the cornea is not abraded, and whenever it is possible the eyes should be used alternately.

It should be remembered that in infants the corneal reflex is not so reliable as in adults, and that in these little patients the absence of reflex movements of the limbs when the skin is pinched is a more certain sign of anæsthesia.

The Size of the Pupil is a useful indication of the depth of anæsthesia. When a patient becomes unconscious the pupils are generally dilated, but as the anæsthesia deepens they contract, and should be kept small throughout the operation. If the pupil becomes very large while the corneal reflex is distinctly present, it is a sign that the patient is coming round, and more anæsthetic should be given. But if no corneal reflex can be obtained, and the pupil becomes dilated, this is generally a sign of danger, and the anæsthetic should be withdrawn till the pupil contracts. A very small pupil, known as the "pin-point" pupil, is often a precursor of vomiting, especially when chloroform is being given, and when the vomiting actually takes place the pupil may suddenly dilate.

Relaxation of the Muscles.—In many operations the utmost degree of relaxation is required. It is often supposed that this can be obtained only with chloroform, but it can also be produced by ether, though sometimes not so rapidly as with chloroform. If a patient is taking ether, and the surgeon requires more relaxation, it may quickly be obtained as a rule by giving a little chloroform.

To obtain satisfactory anæsthesia all the above-mentioned guides should be watched, and one must not be used to the exclusion of the others, or disaster may result.

Condition of Danger.—Besides the obstructed respiration mentioned above, a dangerous condition may arise from any of three causes: (1) An overdose of the anæsthetic; (2) The loss of a large quantity of blood; or (3) The shock of a severe or prolonged operation; and frequently two or more of these causes are combined.

The signs of danger may occur with startling rapidity, as in the case of syncope from an overdose of chloroform, but more commonly the onset is gradual. The breathing becomes more and more shallow, the pulse faster and smaller, the pupil large, with no contraction to light, while the corneal reflex is lost, the eyelids separate, the face becomes pale, the nose feels cold to the touch, and sweat may break out on the forehead. When failure of respiration is the

principal cause of anxiety the breathing will often be noticed to become shallow, or stop altogether, while the pulse remains fairly good; but danger may arise without the possibility of saying whether the pulse or respiration failed first.

In cases of sudden danger treatment must be prompt and thorough. The anæsthetic, of course, must be withdrawn, the mouth opened with a gag, and the tongue drawn forward and held in position by an assistant. A finger should be passed into the pharynx to exclude the presence of any foreign body, such as vomited matter, etc. The patient should then be drawn up the table till the head is just hanging over the end, and if the mechanism of the table permit it, the whole of the body may be raised. Artificial respiration must now be begun by grasping an elbow of the patient in each hand, and compressing them firmly against the chest wall. The arms are then swept upwards and outwards at their full extent till the hands meet above the head, and they are then slowly brought down again and pressed against the chest wall as before. Great help may be given by an assistant pressing against the diaphragm through the abdominal wall at the time that the arms are brought down to the chest, and this movement will be of special use when the chest wall is rigid. It should be remembered that the success of artificial respiration depends on the thoroughness with which the movements are performed, that they should not be made more frequently than sixteen times in a minute, and should be continued for some minutes after all obvious signs of life have disappeared. If oxygen is available it should be administered while artificial respiration is being performed.

Hot cloths should be placed over the præcordium, alternately with cold ones, and strychnine (gr. $\frac{1}{6}$) or ether (20 min.) be injected hypodermically. Brandy may be given hypodermically in a dose of 2 dr., or an ounce with a few ounces of water per rectum.

A faradic current may be passed from the second or third intercostal space in front to the spine behind, and direct stimulation of the heart by massage has apparently saved some lives. The heart will be reached most easily by an incision through the upper part of the abdominal wall, followed when necessary by one through the diaphragm.

When the serious condition of the patient develops more slowly the treatment should be that given under **Shock** (p. 46).

When infants and very little children stop breathing, they should be treated by taking both their feet in the left hand and lifting the patient up till the head just rests on the table. The right forefinger should then be placed in the mouth and used to hook the tongue forward. An assistant now performs artificial respiration by compressing the chest walls firmly and then allowing them to resume their usual position, which their great elasticity enables them easily to do.

IV.—RECOVERY FROM ANÆSTHESIA.

In removing a patient from the operating-table to the bed, he should be disturbed no more than is absolutely necessary, as want of care in lifting and placing in bed is likely to produce vomiting. The bed should have been previously warmed with hot water-bottles, but these must be taken out before the patient is moved from the operating-table. They may be replaced, when necessary, when the patient is fully conscious. During the return to consciousness the patient should be kept in a darkened room, and as quiet as possible. He should be prevented from talking, and seeing relations and friends, as any of these causes of excitement will generally be followed by severe headache. The room should be warm, and well ventilated, so that the smell of the anæsthetic may be removed, but the patient must not be placed in a direct draught, as this has been the cause of bronchitis in patients who have inhaled ether for a considerable time. If the surgeon does not object, it is well to place the

patient on one side with a pillow pushed against the back, and after a time he may be turned on to the other side. When there is much blood in the mouth, as after the removal of adenoids, etc., or when vomiting is taking place, an almost prone position is the best.

It should be remembered that some patients are less inclined to vomit when they are well propped up in bed.

No food should be given for four hours after the anæsthetic, or even for longer, if the patient will wait. Most of the vomiting after anæsthesia is caused by injudicious preparation, or through giving food by the mouth too soon after the recovery. After an unimportant operation some weak tea is the most suitable liquid to begin with, and if this is taken without any discomfort a little food may be allowed in an hour.

After severe and important operations on the abdomen the after-feeding of the patient is a matter of great importance, and one which is in the hands of the surgeon, and not of the anæsthetist.

Vomiting is more common after ether than after chloroform; but after ether it generally occurs early, before consciousness returns, and after the first clearing out of mucus, with perhaps a little bile-stained fluid from the stomach, it will often not recur if nothing is given by the mouth for four hours. Vomiting after chloroform, on the other hand, often does not begin till the patient has been quite conscious for a few hours, and is then the result of taking food. Some patients are much more inclined to vomit than others, and the longer they will go without taking anything by the mouth the better chance they have of an uneventful recovery.

Vomiting should be treated by small doses of hot water, given in an earthen-ware spoon so that the lips may not be burned, for the water should be as hot as can be taken, as warm water is more likely to encourage the vomiting. When a small dose of water does not relieve it, a tumblerful may occasionally do so. Some patients do better with sips of iced soda-water or champagne, or sucking small pieces of ice. Some persons find the taste of ether diminished by sucking peppermints.

Thirst is best treated by washing the mouth out with water containing some lemon juice, and by giving rectal injections of hot water.

Bronchitis is generally the result of exposure, except after operations in the mouth, when it may be caused by the inhalation of septic material from the wound. It must be treated on ordinary lines.

Shock.—During a severe operation, or at its conclusion, the patient may be found in a state of shock, with small rapid pulse, shallow breathing, cold nose, etc., and very careful treatment is sometimes necessary. The foot of the operating-table or bed should first be well elevated on blocks or boxes, and the limbs covered with cotton-wool and bandaged. The patient must be made as warm as possible by hot-water bottles, and the room must be kept thoroughly warm. Saline fluid should be given by the rectum, or into the axillæ or thighs; but if the shock is severe, intravenous infusion is best; and adrenalin (1–40,000) may then be added to the fluid. Strychnine and alcohol have fallen into disrepute, but a hypodermic injection of pituitary extract is often useful. Inhalation of oxygen, with gentle artificial respiration, may also be of assistance.

If the patient recovers from the shock, and the operation is continued, “open” ether should be given as the anæsthetic. (See also SHOCK, SURGICAL.)

V.—THE CHOICE OF AN ANÆSTHETIC.

The relative safety of the various anæsthetics should first be considered. Nitrous oxide gas has been attended by so few fatalities in proportion to the

enormous number of times which it has been administered, that there can be no hesitation in describing it as the safest anæsthetic at our disposal. Many statistics have been drawn up to compare the relative safety of chloroform and ether, and the result is that ether may be reckoned to be five times as safe as chloroform, mixtures of chloroform and ether taking a place between the two drugs used separately. Ethyl chloride was at first vaunted as perfectly safe, but so many deaths have been recorded—and many have occurred which have not been recorded—that its exact position in this respect must be reconsidered. It is certainly much more dangerous than gas, probably more dangerous than ether, and approaches chloroform in its death-rate, even if it does not equal it.

Putting aside those short operations in the mouth such as the removal of teeth, and considering the longer operations for which ether, chloroform, or one of their mixtures is required, we must consider the age of the patient, his general condition and state of health, and also the nature and probable length of the proposed operation.

As regards **Age**, it may be stated that, as a general rule, ether should be given to patients over six and under sixty. For infants up to the age of three, pure chloroform is the best anæsthetic; from three to six, a mixture of chloroform and ether; from six to ten, ether preceded by a little mixture; from ten onwards, ether, preceded by gas if the "closed" method is chosen, or by the "open" method, up to about sixty; and over sixty, a mixture or pure chloroform.

General Condition.—Those suffering from any acute congestion of the respiratory tract should not take ether, but must have chloroform, and ether is best avoided when there is marked degeneration of the arteries. In all cases of bad heart disease, and where an aneurysm exists, a closed inhaler should not be used. The best plan for these cases is to begin with a mixture of ether and chloroform on a Skinner's mask, and when this is tolerated, the Rendle's mask with a stronger dose may be substituted, pure ether instead of the mixture being poured on to the sponge when more stimulation is considered necessary, or ether alone may be given by the "open" method. Persons suffering from severe shock after an accident do not require much anæsthetic, and for them ether is the best. Patients with marked albuminuria should have chloroform.

The Operation.—For dental cases and other short operations on patients sitting in a chair, such as the removal of tonsils or adenoids, the choice lies between nitrous oxide, ethyl chloride, and gas and ether. For the majority of these cases there is no drug so satisfactory as nitrous oxide given with some air or oxygen. With it an average anæsthesia of half a minute can be expected, with a speedy, pleasant recovery. Ethyl chloride will give a longer period of anæsthesia, but it is not so safe as gas, and the recovery from it is likely to be followed by headache and vomiting, especially if a large dose has been given. Some anæsthetists prefer ethyl chloride to gas for children, as they are often very restless in the chair, and too frightened to allow the face-piece to be fitted accurately. When this is the case it is much more convenient if the operation can be done in the recumbent posture, as small patients so easily slip into a bad position when anæsthetized in a chair: ethyl chloride will then be safer, and a better anæsthesia will be obtained.

If an anæsthesia of two or three minutes is required for the extraction of difficult or numerous teeth, this may be obtained by means of gas given by the nasal method; but as some practice is required before this can be used satisfactorily, it is better for those who give anæsthetics only occasionally to have recourse to gas and ether, which may quite safely be administered to a patient in a sitting posture.

On no account whatever should chloroform, or any mixture which contains

chloroform, be given to a patient sitting in a chair ; if gas or ether is unsuitable, or not available, and chloroform is to be given, the patient must lie on a couch or bed. Neglect of this precaution has been the most fruitful cause of deaths under chloroform.

Apart from short operations in the mouth, in which the anæsthetist's apparatus must as a rule be removed before the operator can begin, there are many small operations, such as the opening of abscesses, removing nails, or very painful dressings, for which gas may be used with great advantage. Care must be taken that the gas be not unduly pushed, so that the patient becomes cyanosed and jactitates ; air must be given frequently by opening the lower slot for a breath or two, or the face-piece may be removed from the face. For these short cases gas and oxygen given with Hewitt's apparatus is the best method. If gas is not available, ethyl chloride may be given ; but the longer the anæsthesia required, the less advantage is there in choosing gas or ethyl chloride instead of ether or chloroform.

When the operation is to last more than three or four minutes, the choice of the anæsthetic should be limited to ether, chloroform, or a mixture of the two. On account of its greater safety the claims of ether should first be considered, and for the majority of operations it should be the routine anæsthetic, preceded, of course, whenever possible, by nitrous oxide when the "closed" method is employed. When secretion of mucus and saliva becomes excessive, or the breathing is so deep that the operator is troubled, a change can be made to chloroform or a mixture.

There are occasions when ether should not be chosen : (1) When it would be unsuitable on account of the congestion it produces, as in operations on the brain, removal of the thyroid gland, operations on the eye, etc. ; (2) When it would increase the difficulties of the operator through the secretion of mucus and saliva which it often produces, as in operations on the mouth and larynx ; (3) When the ether apparatus would be in the way of the surgeon, as in operations on the face : but here the anæsthesia may sometimes be begun with ether, and a change to chloroform made later ; (4) When a cautery is to be used near the face ; (5) When relaxation of muscular spasm, combined with light anæsthesia, is required, as in painful labour, eclampsia, and tetanus ; (6) For some abdominal operations in which a very deep anæsthesia, with perfect relaxation of muscles, is necessary, as in operations on the gall-bladder, etc. But after some practice, and especially if the patient has had a preliminary injection of morphia and atropine, so satisfactory an anæsthesia may generally be obtained with "open" ether that it may be recommended as a routine anæsthetic for abdominal operations.

VI.—LOCAL ANÆSTHESIA OR ANALGESIA.

When the practitioner is single-handed, the administration of a general anæsthetic for an operation, however simple, should not be attempted. When the general condition of the patient is extremely serious, or the operation to be performed is trivial, the freedom from pain may be obtained by local instead of general anæsthesia. The decision as to whether general or local anæsthesia should be employed depends on the nature of the operation, the practitioner's experience of the various methods, and the mental condition of the patient ; but in this country most people, and indeed most surgeons, prefer general anæsthesia to local.

Analgesia may be obtained in several ways : by cold, by local application, by the "infiltration" method, and also by spinal injections ; as the latter method is not in general use it will not be described here.

Freezing.—The skin may be frozen by means of two parts of pounded ice and

one part of salt mixed together and applied to the part in a rubber bag. The skin, when frozen, becomes white and hard. Freezing may also be done with an ether spray, but the best way of producing analgesia by cold is by a spray of ethyl chloride. In using this it is important that the nozzle of the bottle should be small, and that it should not be held too near, so that only a fine spray falls on to the part to be frozen. This method of analgesia by cold is only suitable for simple operations, such as the opening of an abscess, and pain may be experienced when the skin thaws.

Local Application.—The drugs most commonly employed to produce local anæsthesia are cocaine hydrochloride, or eucaine hydrochlorate dissolved in water. For operations on the eye, a 4 per cent cocaine solution will be sufficient, a little being dropped into the eye at intervals of two minutes, and in ten minutes the operation may be performed. Soluble tabloids are now sold which may be placed under the lid, instead of a solution. For the mucous membrane of the mouth and nose, a 4 or 5 per cent solution may be used in a spray; or a small piece of cotton-wool or a strip of gauze, soaked in this solution, to which a few drops of 1–1000 adrenalin may be added, may be applied to the part and left there for five minutes; or a strong 10 per cent solution may be painted on the part. This 10 per cent solution may be used also on the gums to prevent the pain of several dental manipulations. For the extraction of teeth, local anæsthesia is now frequently employed, but for details of the method a book on dental surgery should be consulted. For the passage of a catheter, the urethra may be made insensitive by a 2 per cent solution, used in a special syringe.*

The skin cannot as a rule be rendered insensitive without a solution as strong as 20 per cent, and better results will be obtained with infiltration; but for the removal of minute tumours, a few minims of a 5 or 10 per cent solution may be injected into the tissues round the base, and this method will also be of service in treating crushed fingers. Some surgeons apply a rubber band to the base of the finger with the object of confining the cocaine to the part.

Some persons are very susceptible to cocaine, and soon show symptoms of poisoning. Among the most usual of these are giddiness, with great difficulty in breathing, and a feeling of oppression. The patient becomes pale, with dilated pupils, and a slow and feeble pulse. Occasionally restlessness and irregular convulsive movements, or delirium, will be observed. Dangerous symptoms are less frequent when the patient has had food or a stimulant before the application of the cocaine, and so operations under cocaine are better performed after than before a meal. When the signs of poisoning are noticed, the patient must be laid on a couch with the feet elevated. All clothing which hinders respiration must be loosened, ammonia or nitrite of amyl held to the nostrils, and occasionally artificial respiration may be required. The patient should be kept warm by hot bottles, but the windows should be opened to allow a free supply of air. As soon as he can swallow he should be given hot tea, coffee, or brandy, and should not be allowed to sit up till he is feeling quite recovered.

Eucaine is much safer than cocaine, and should be used in a 4 per cent solution in water.

Infiltration.—For small operations under local anæsthesia, the infiltration method is the best. A solution should be prepared consisting of β eucaine 1 part, sodium chloride 8 parts, water 1,000 parts. This solution may be sterilized by boiling without affecting the eucaine. A convenient method of making the eucaine solution is to have prepared some gelatine capsules, each containing β eucaine 0.2 grams, sodium chloride 0.8 grams; the solution is made by dropping one of these capsules into 100 c.c. of boiling water, and allowing it to

* It should not be forgotten that sudden death has followed the introduction of cocaine into the urethra.—AMERICAN EDITOR.

cool. A 2 per cent solution of novocain is frequently used with good results. Adrenalin (1-1000), in the proportion of 3 minims to a drachm, may with advantage be added to these solutions, as it constricts the vessels and so diminishes bleeding, and limits the analgesic effects to the region injected.

A syringe in good working order, and capable of holding 10 c.c., should be sterilized and filled with solution. The skin having been painted with iodine, the needle is inserted into the skin (not under it) and a few drops of the solution injected. A wheal will be produced, and the syringe is removed and inserted at the side of this, and a few more drops of solution injected. This is repeated till the whole area of the skin which it is desired to render analgesic has been made œdematous with the fluid. Some of the solution is then injected hypodermically (under the skin), and into the deeper structures if the operation requires this. The incision may be made after twenty minutes, and the analgesia will last about that time; but if the operation is prolonged, more of the solution may have to be used from time to time.

The œdema produced by infiltration considerably alters the appearance of the part, and suppuration after operations performed in this manner is not unknown; and the practitioner is advised to restrict its use to the removal of small tumours of the skin till he has had some experience of the method. But with practice most minor surgical operations can be done by this means, and some surgeons use it for more important operations, such as herniæ, etc., and use deep injections for the treatment of fractures and dislocations.

There is little risk of poisoning either with eucaine or novocain; as with cocaine, it is better that the patient should have had some food not long before.

It must be remembered that it is most difficult to render an inflamed area analgesic by local means, and that death from œdema of the glottis has followed infiltration of the structures round the tongue. Children are unsuitable subjects for this method, and many nervous persons will object to it.

R. J. Probyn-Williams.

ANEURYSM, SURGICAL TREATMENT OF. — A brief consideration of two conspicuous facts in connection with the natural history of aneurysm will at once lead us to the subject of treatment. One of these is the general tendency which exists towards rupture of the sac. It emphasizes, of course, the necessity for surgical interference whenever possible. The other is that spontaneous cure can occur. The methods by which this is brought about in nature are precisely those which we endeavour to reproduce artificially by means of surgery. There is no method of treatment known to us which is not an imitation of some strictly spontaneous curative process. Nature's means of effecting a cure, and our imitations of them, may be thus enumerated and compared. They are:—

1. Spontaneous deposit of clot in the aneurysm brought about by diminished flow through the vessel, or disturbance of clot causing a block in the afferent or efferent vessel. In treatment, compression or ligature of the vessel, and manipulation for the detachment of emboli, represent these processes.

2. Suppuration and gangrene, with obliteration of or destruction of the sac. These are imitated by the Matas operation or by excision.

3. Pressure on the artery of supply by the aneurysmal tumour. This is represented in treatment by flexion of the limb.

4. Inflammation round the sac, which spreads to it and causes thrombosis. A counterpart of this condition is obtained by means of irritating injections around the sac.

The most important, because the safest and most generally applicable, methods of treatment are those which bring about active or passive clotting in the aneurysm, through lessening or arresting the circulation in the vessel above, and in the tumour. Certain methods which have been employed, but are now

abandoned or seldom used, may be first mentioned. They ought not to be lost sight of, for some of them may, and probably will, in the future prove to be capable of more successful application than in the past, and history has revealed, in surgery as elsewhere, a well-known tendency to repeat itself.

Injection of the Sac by Coagulating Fluids has offered most promise, but the risks of embolism, inflammation, and sloughing of the sac have been found dangers serious enough to discredit the method. Tincture of perchloride of iron injected drop by drop from a screw syringe has been most commonly used.

Introduction of Foreign Bodies into the Sac.—Wire, horsehair, silkworm gut, catgut, etc., have been introduced into the sac with the object of producing coagulation of its contents. In some cases metallic wire and electrolysis have been combined, and a very few favourable results have been recorded. This operation should be reserved for otherwise hopeless cases.

Galvanopuncture has proved no more successful in the treatment of surgical aneurysm than in that of internal cases (for details see Dr. Drummond's note, under ANEURYSM, THORACIC, *infra*). It may be well to mention that many deaths have resulted from surgical defaults and from cellulitis in the neighbourhood of the punctures.

Parenchymatous Injection of Ergotine.—The mixture suggested is: Extract of ergot, one part; rectified spirit and glycerin, of each one and a half parts. This is injected with an ordinary hypodermic syringe (10 to 15 min.) into the tissues surrounding the aneurysm, but not into the sac. If after two or three injections there is no improvement, it is useless to persevere.

Manipulation.—The sac is emptied by gentle and continued pressure. Its walls are then rubbed together in order to detach some portion of the lining clot, in the hope that the afferent or efferent vessel may be plugged by it, or that the detached clot should increase its size *in situ* by fresh deposit upon its surface. The fear of embolism has interdicted this form of treatment.

Needling of the Interior of the Sac (see ANEURYSM, THORACIC) is the most promising of all methods under present consideration, and is specially likely to prove a useful addition to methods of compression.

I.—PRESSURE TREATMENT.

Of all means, apart from operation, pressure is by far the most important in the treatment of aneurysm. The compression may be applied *directly* to the aneurysm, or *indirectly* to its vessel of supply.

Direct Pressure.—Used in unsuitable cases, this has done much harm. On the other hand, it has proved most serviceable as a curative agent in cases where clotting was first brought about by indirect pressure, or by ligature above the sac, but where, nevertheless, pulsation had returned later on. Careful watching is necessary, and the pressure must not be severe enough to cause sloughing or ulceration of the skin over the sac.

The application of this method of treatment, say to a popliteal aneurysm, would be as follows: The limb is bandaged from the toes to below the knee, a well-padded splint is fixed to the front of the leg and thigh, reaching from the groin above to the ankle below, and leaving the aneurysmal tumour and popliteal space exposed to view. A thick compress, such as a well-wrung sponge, should be firmly but not tightly bandaged as a pressure pad over the swelling, and the whole limb should be elevated to at least half a right angle. The toes below should be frequently examined to determine the condition of the circulation. Pain of any severity demands removal of the bandages.

Indirect Compression.—This being the most important method of treatment apart from operation, its principles are to be remembered, and should be considered in detail.

Either by fingers or instruments the circulation can be pressure-controlled, whether on the proximal or the distal side in the majority of aneurysms.

By pressure on the proximal side control may be made complete or incomplete. The object of the former is to fill the sac with clot suddenly (the passive clot) ; of the latter, to allow of the gradual deposition of laminated clot (the active clot). Complete control is usually so painful as to require anæsthesia, and it may be some hours before clotting in the aneurysm occurs. If hardening of the aneurysm shows that consolidation is taking place, the case is hopeful, and with care it is likely that a cure will be brought about. So soon as consolidation has occurred, the pressure may be slightly relaxed, but it should be maintained in such a manner as to diminish the force of the blood-current for at least five hours, during which the newly-formed clot has a chance of consolidating. Even after definite hardening and arrest of the pulsation in the aneurysm, it is possible for the clot to be dissolved and washed away, and for pulsation to return. Rupture of the aneurysm has been known to occur shortly after the commencement of this treatment, and a rapid increase in the growth of the swelling is a danger signal which must not be allowed to pass unheeded.

To carry out this treatment satisfactorily relays of assistants are required. There should be one to observe the condition of the aneurysmal tumour, a second to compress the vessel, and a third ready to take the place of one or other when fatigued. A shot bag or other weight suspended over the fingers is an aid, but the duties are nevertheless so fatiguing that it is necessary to have a change of assistants every three or four hours. The patient ought to lie comfortably, and the surface points over which pressure effectually controls the circulation should be marked out as an aid to relieving the skin from too continuous pressure on one spot.

It is impossible to predict the cases in which this treatment will succeed, or how long it may require to be continued.

The chief advantages of digital over instrumental pressure are, that it can be more easily regulated, because it allows of slight changes in position of the pressure-points upon the skin, and so diminishes the risk of pressure-sore ; that it is less painful ; and that it gives better opportunity for avoidance of pressure on the accompanying vein. It is chiefly applicable in cases of high carotid, axillary, femoral, popliteal, and brachial aneurysms. Pressure can be kept up so long as it is borne without great inconvenience, but it is usually necessary to discontinue it at night and allow the patient to sleep. During the intervals of rest a supporting pad and bandage may be worn in order to diminish the activity of the circulation in the aneurysm ; or in the case of a popliteal, or of a brachial aneurysm at the bend of the elbow, flexion of the limb secures the same result. Success may be attained by this method after months or even years of trial. The greatest success has followed continuous pressure and entire arrest of the circulation through the aneurysm for a limited number of hours.

Many instruments on the tourniquet principle have been employed in place of fingers to compress the artery while avoiding pressure on any accompanying vein, and allowing, usually, of the passage of a continuous weak and diminished stream through the sac. When using such instruments the limb below the aneurysm should be bandaged, and the contact point of the pressure-pad shifted from time to time to prevent damage to the skin.

Cure may be gradual, as shown by the aneurysm getting harder, and pulsation and expansion diminishing ; or it may be sudden from filling up of the sac with clot. The patient requires careful and constant skilled supervision. The most courageous and obedient are apt to lose patience when restricted to one position in bed, while they are enduring pain and suffering from loss of sleep

and exhaustion. The use of morphia or of some other sedative is necessary in the majority of cases, and even with these aids it may still be impossible for the patient to tolerate the treatment.

Rapid Pressure Method.—This was first applied to the abdominal aorta by Dr. William Murray, of Newcastle-on-Tyne, and with success. It has since been used for aneurysms of the limbs. A degree of pressure sufficient to arrest pulsation in the sac is brought to bear on the vessel above the aneurysm for a period varying from eight to eighteen hours. Few patients can tolerate the necessary pressure without narcotics, and if morphia does not suffice it is necessary to use chloroform, though the anæsthesia need only be light, and can be maintained for several hours if opportunities for feeding are provided for.

Reid's Method.—The principle in this method is to produce rapid coagulation of the blood, which is made to fill the aneurysm and its vessel of supply. Taking popliteal aneurysm as an example, it is carried into effect thus: An elastic bandage is firmly applied from the toes to the lower border of the tumour; a second from a short distance above the tumour to the thigh, leaving the aneurysm and a small portion of its vessels unemptied and unsupported; then above the upper bandage an indiarubber tourniquet is fixed round the limb, firmly enough to arrest the circulation, and the bandages below are removed. The tourniquet must be kept in position for an hour, during which the limb should be pulseless. Meanwhile the aneurysm must be carefully watched, and if it enlarges, support must be given to it by pad and bandage. Before removal of the tourniquet, arrangements will be made for compression of the artery above by digital or instrumental pressure. For aneurysms higher up than in the instance we have been considering, the use of a tourniquet may not be possible; the artery above is then controlled by digital pressure. Digital pressure is also to be maintained whilst the tourniquet is removed, when the surgeon who is feeling the aneurysm dictates how much the pressure is to be relaxed. If the tumour appears to have consolidated completely, a continuous pressure on the femoral artery for three or four hours will suffice to cure it in a majority of cases, but the circulation should be lightly controlled by digital pressure for three or four days. If some pulsation be still perceptible, the cure may be completed by direct pressure on the aneurysm, as previously described; or, if no effect have been produced, the attempt should be given up for the time, and another made after a week of rest, or some other method of attack chosen.

In the early stage of the application much pain may not be complained of, but in a short though varying time it becomes intolerable, and either morphia, or chloroform, or both, are needed. Careful watch must be kept on the pulse as a guide to the state of the general circulation, and on the toes in order to detect the premonitions of gangrene.

Compression by Flexion of the Limb.—In aneurysms, by choice at the bend of the elbow or in the popliteal space—especially of the sacculated variety, and with thick sac wall—if moderate (not forcible) flexion of the limb produces arrest of pulsation, a cure can be brought about by maintaining that position. The same method can aid the cure in consolidation started by other means.

As regards selection of cases, fusiform aneurysms are never favourable; sacculated aneurysms, only when the mouth of the sac is not large enough to allow of active circulation in the tumour; popliteal and brachial (at bend of elbow) are the cases most suited to pressure by flexion of the limb. It is to be avoided in cases of thin-walled aneurysms which are increasing in size. Those in the groin and axilla are seldom benefited by it, and large aneurysms in the groin have been ruptured by flexion of the hip.

Pressure on the Artery above, of such degree as to diminish but not to arrest the circulation, is most likely to succeed when the swelling is hard and the

pulsation not forcible, i.e., where some clot has already been deposited in the sac, and when the patient is intelligent and placid enough to aid in the treatment.

Total Arrest of the Circulation by pressure on the artery of supply is used in cases of abdominal, inguinal, and carotid aneurysms, i.e., in situations where prolonged pressure cannot be borne, and where the artery can be effectually compressed against a bony prominence. It has also been used successfully for aneurysms of the limbs of patients unable to tolerate the more gradual method. The elastic bandage and tourniquet method is useful in recent aneurysms which are not too rapidly increasing in size and are not too thin-walled, and where the heart is not diseased and the arteries are not exceptionally rigid.

The objections to pressure treatment are:—

1. That it is painful. Some patients cannot bear it in the most moderate degree, and all find a prolonged course so exhausting as to be almost, if not quite, intolerable.

2. That it may not cure the aneurysm. Even after months of determined effort and painful experience, a considerable proportion of patients will not be cured.

3. That after "cure" there is some tendency to relapse. It may be after a few hours or after a few weeks that pulsation returns in the aneurysm.

4. That the treatment is dangerous: (a) Rupture may take place soon after the treatment is commenced, or rapid extension of the swelling point to its probable occurrence; (b) Gangrene of the limb below may occur, probably in some cases from pressure involving the vein as well as the artery, though it is only fair to state that gangrene is a danger common in greater or less degree to all forms of treatment.

5. Suppuration of the sac may happen in cases where the aneurysm has been suddenly "cured" by the formation of a passive clot.

6. Sepsis. All sorts of septic-wound complications have followed sores produced by too active or too prolonged pressure over the vessels.

7. Subsequent operation may be made more difficult owing to the formation of pressure sores; or because pressure may have increased the collateral circulation to such an extent as to make operation a failure; or through the vessels being so matted to their surroundings after prolonged pressure as to make ligature a serious and difficult proceeding.

It may be said in conclusion, that while these methods have all proved useful in the past, and in days when operations were dreaded by patients on account of pain and by surgeons through fear of sepsis, their scope now has become greatly limited, and their use restricted to exceptional cases which promise to respond readily to such treatment.

II.—OPERATIVE TREATMENT.

The "Matas" Operation.—The design of this, for the present the ideal operation, is to open and empty the sac, and in fusiform aneurysm to obliterate it by a series of tier sutures, but in saccular ones to close the opening into the vessel, and then obliterate the sac by tier sutures, leaving a sufficient channel for the circulation. The operation produces the same result in a quarter of an hour as the processes of nature would take many months to accomplish. I am now convinced that this is, so far, the best operation devised for the cure of aneurysm, when satisfactory control of the circulation, as in the limbs, can be effected.

Suture of the Aneurysmal Openings into vessels, after the separation of the latter by dissection, has met with its most useful application in the case of arteriovenous aneurysm, but for both these new methods there will be a larger place in the future.

Excision of the Sac.—My last experience of excision of a popliteal aneurysm has made me less enthusiastic than I then was as to the universal applicability of the popular method of excision of the sac.

The patient was a vigorous-looking man with a small but leaking popliteal aneurysm, which was easily dissected out. The artery above the aneurysm was so soft and brittle that a thick catgut ligature cut through it like cheese. Another was applied higher up. This held. I was so impressed by the brittleness of the vessel that special nurses were told off to watch for hæmorrhage. The third day after the operation profuse hæmorrhage occurred, and the femoral artery was successfully tied in Hunter's canal. On the following day gangrene of the foot had set in, and amputation was performed through the thigh. The patient recovered, but lost his leg. Further experience has taught me that this man could have been safely cured, and that his leg would have been preserved, by the obliterative endo-aneurysmorrhaphy method of Matas. The case recorded is of interest, as it emphasizes the old view, which has latterly been ignored and even denied, that the vessels in the neighbourhood of the sac are occasionally so brittle and diseased that there is danger in applying a ligature to them.

Statistics show the safety of excision of the sac. It is also proved that there is less chance of gangrene following it than is the case with an operation by ligature; that the cure is certain; and that no after troubles, such as arise from the presence of a shrunken sac, are possible. The most brilliant application of this method of attack has been found in the treatment of ruptured diffuse aneurysms of the limbs where amputation used to be the only alternative. By turning out the escaped blood and finding and excising the aneurysm, many of these serious cases can be brought to a successful issue. Even in these cases the operation has been displaced by the operation of Matas, which can be done without serious disturbance of the surrounding parts.

Ligature of the Artery of Supply.—This may be (1) *Proximal*, immediately above the aneurysm, or some distance above it; or (2) *Distal*, below the aneurysm.

1. *Proximal Ligature.*—In all but exceptional cases, the nearer a ligature can be applied above the aneurysm the better, so that the obstruction in the aneurysm and that in the vessel affected by the ligature may combine. The immediate effect of the ligature is to arrest pulsation in the sac, which shrinks and should become solid. The diminished circulation in the limb below demands treatment by warm wrapping, elevation, artificial maintenance of heat, and prolonged, frequently-repeated upward rubbing, in order to aid the venous circulation. Following ligature there may be:—

a. Recurrence of pulsation. In the course of a few days after successful ligature pulsation may recur in the aneurysm, but as a rule it disappears in a few days more, of its own accord, or with slight aid. Bandaging the elevated limb and compression of the aneurysmal swelling may first be tried. Then digital pressure upon, or ligature of, those collateral branches which have influence upon its pulsation; or ligature of the artery distal to the sac may be resorted to. If a fair trial of these means fail, the Matas operation is indicated.

b. Gangrene. If the limb continue to be shrunken, pallid, and cold, definite gangrene is to be expected before the end of the first week. If the gangrene be dry, the whole extremity may, after thorough cleansing, be wrapped in antiseptic wadding, and the appearance of a line of demarcation awaited. If the gangrene be septic and moist, the sooner the limb can be amputated above the aneurysm the better.

c. Suppuration in the sac. The ordinary evidences of pus formation in the sac indicate the same treatment as for suppuration elsewhere. It should be freely opened, its contents evacuated, its interior packed. If inflammation

has not extended from the sac into the surrounding tissues so as to make excision impossible, this will be the best treatment. Amputation will offer the best chance if secondary hæmorrhage after suppuration should occur.

2. *Distal Ligature*.—The only condition in which this has been employed with encouraging success has been in aneurysms of the lower part of the common carotid artery.

Recent advances in blood-vessel surgery justify the expectation that, in the near future, cases in which the blood-vessels on either side of the aneurysm are fairly healthy will be treated by excision of the sac and restoration of the vessel by the transplantation of a graft.

Surgical aneurysm is the result of syphilitic disease of the blood-vessels almost as frequently as medical aneurysm. If there is a history, or other evidence, of this disease, including a positive Wassermann reaction, treatment of the aneurysm should be followed by an antisymphilitic course.

ANEURYSMAL VARIX AND ARTERIOVENOUS ANEURYSM.

The dangers and difficulties of operation in such cases, where large vessels are involved and where the circulation is difficult to control, must be fully realized; yet the dangers and discomforts resulting from the lesions may be so serious that the risks of operation have to be faced. In cases of aneurysmal varix, palliation may be obtained by the use of an elastic bandage, and occasionally a pad over the orifice of communication can be so effectually applied as to remove all the distressing symptoms. When, however, a tumour is present, operation is a necessity, for the aneurysmal swelling is progressive and will eventually rupture. The operation usually implies separating the artery and vein, and tying both vessels above and below the opening. After separation it may be possible to close the opening in each by carefully applied sutures, and this is the best surgery.

ANEURYSMS OF THE UPPER EXTREMITY.

Axillary Aneurysms.—On account of their rapid growth, the serious pressure symptoms they occasion, and their liability to rupture, active treatment is essential. There are four methods of attack, from which a choice must be made: (1) *Pressure*; (2) *Ligature of the Artery above the Aneurysm*; (3) *Excision of the Sac*; (4) *Matas' Operation*.

1. *Pressure* is so painful as to necessitate the use of an anæsthetic, and relays of assistants are required in order to hasten the result. The method of application is as follows: The spot above the clavicle on the third part of the subclavian artery, pressure on which completely arrests the circulation in the aneurysm and in the vessels below, is to be noted and marked. Then an elastic bandage is applied firmly to the limb from below up to the axilla, but not over the aneurysm. By pressure on the third part of the subclavian the circulation in the aneurysm must be totally arrested, and the elastic-bandage pressure should be maintained for one hour, after which digital pressure should be continued for three hours more, and then gradually relaxed.

In fat or unusually muscular subjects it may be impossible to control the circulation with the skin undivided. It would be possible and proper in such a case to make the pressure through a wound over the vessel. It is almost superfluous to add that such a wound could be safely made only under perfect surgical conditions, and that those who compress the vessel would necessarily wear sterile indiarubber gloves.

2. *Ligature of the Artery above the Aneurysm*. If the aneurysm involves the lower part of the artery it will be possible to ligature the artery above it, but as a rule, even in these circumstances, the operation of choice will be by ligature

of the third part of the subclavian, as the dangers and difficulties of the latter operation, when in the hands of a skilled surgeon, are now comparatively small, and the after-results fairly good.

3. *Excision of the Sac.*—This is still regarded as a last resource by the majority of surgeons, but evidence is accumulating in its favour. It should be the method of choice in dealing with large, rapidly increasing aneurysms which are causing œdema and paralysis of the limb.

4. *Matas' Operation.*—If the circulation can be satisfactorily controlled, Matas' operation would be better than excision of the sac.

Brachial Aneurysm.—Compression here is easily performed, and should be fairly tried. For cases at the bend of the elbow, flexion is the method of choice. For those due to traumatism and embolism, excision is the only satisfactory treatment. It is certain that, unless prolongation of the operation for any special reason is undesirable, excision of the sac should be followed by blood-vessel grafting.

Aneurysm of a Palmar Vessel.—Compression of the aneurysm and of its arteries of supply, along with elevation of the limb, may first be tried. A splint is to be applied over the extensor surface of the hand and forearm, and pressure pads adjusted over the radial and ulnar arteries and over the tumour. The hand and arm are then slung at a right angle. If this does not succeed, it will be necessary to ligature the radial and ulnar and to compress with pads the interosseous and median arteries, and to elevate the limb. Excision in the palm is difficult, and may occasion irreparable damage to the usefulness of the hand.

ANEURYSMS OF THE LOWER EXTREMITY.

In this region popliteal aneurysms are the most common. They outnumber those of the femoral artery in the proportion of four to one. Below the popliteal, aneurysms are rare.

Femoral Aneurysm.—Compression treatment by means of elastic bandaging may be tried before operation is resorted to. (*Vide pp. 52, 53.*)

If pressure treatment fails, then the Matas' operation, ligature of the artery above the aneurysm, or excision of the sac, must be resorted to.

Popliteal Aneurysm.—Pressure and flexion of the knee are methods of treatment frequently successful, and comparatively free from danger. They are therefore deserving of fair recognition. (*Vide pp. 52, 53.*) At least 50 per cent of popliteal aneurysms can be cured by pressure.

Ligature of the femoral artery at the apex of Scarpa's triangle is the easiest of the ligature operations for popliteal aneurysm, and it has yielded good results, about 80 per cent of cures having been effected by its means. It seems probable that ligature of the femoral artery in Hunter's canal, or of the popliteal above the aneurysm, might give results even better than these.

Excision of the sac is necessary if the aneurysm is not cured by one or other of the ligature operations above mentioned, or if, after cure, it is the cause of painful contraction symptoms. The Matas' operation or excision of the sac is, moreover, the only alternative to amputation when the sac has ruptured. Under suitable surgical conditions, the Matas' operation should be done for all popliteal aneurysms.

Gluteal Aneurysm.—It is to be remembered that a gluteal aneurysm, owing to its progressive tendency, always demands active surgical treatment. The most successful method of attack as yet reported has been by the injection of a solution of perchloride of iron (20 per cent) into the sac. (Solution of ferric chlorid, U.S.P., contains 29 per cent of the anhydrous salt.) This does not seem to have been followed by serious consequences. The injection (50 minims) is introduced at several places, a few drops at each, whilst the sac is compressed laterally. Rest should be enforced for ten days afterwards.

Incision of the sac, arrest of hæmorrhage by finger pressure, and, after the necessary dissection, ligature of the vessel above and below the aneurysm, is an operative procedure which has been successfully carried out. It would be safer to ligature the internal iliac artery, though even this may not succeed.

Abbe did a Matas obliterative operation with success after passing a ligature round the internal iliac artery to control temporarily the circulation in the aneurysm. It is probable that this is the operation of choice, but the undertaking is a responsible one.

Aneurysm of the Leg and Foot.—These are encountered but rarely. The most satisfactory treatment is by excision of the sac.

ANEURYSMS OF THE NECK.

Aneurysm of the Common Carotid Artery.—When the aneurysm is at its most common site, i.e., at the bifurcation of the artery, the surgical methods of treatment available are: (1) *Digital Pressure*; (2) *Needling the Sac*; (3) *Ligature of the Artery below the Sac*; (4) *Excision of the Sac*; (5) *The Matas Operation*. Before one or other of the above operative procedures is selected, the medical measures described in connection with thoracic aneurysm should have been given a fair trial, since they have at least arrested the progress of the aneurysm for a time. Surgical interference should be resorted to only when threatening signs are present.

1. *Pressure.*—Digital pressure on the vessels below the aneurysm and against the soft parts covering the spine is the best form of surgical treatment, but can seldom be brought to a complete conclusion, nor indeed be tolerated in most cases for any protracted period of time. Daily repetitions are necessary, and should be continued for as long as they can be borne. The development of cerebral symptoms, such as loss of consciousness, convulsions, or paralysis, may necessitate abandonment of the procedure. The pressure method of treatment is most likely to be successful with young subjects, and in cases of traumatic aneurysm.

2. *Needling of the Sac* may be used either in addition to the above method (pressure) or as an independent procedure.

3. *Ligature of the Artery below the Sac* has been associated with a high rate of mortality, chiefly in consequence of disturbances in the cerebral circulation, and apart from this has in some cases not cured the aneurysm. It is therefore at the present time an operation not in favour.

4. *Excision of the Sac* is probably less dangerous than ligature of the artery below, and if it can be accomplished the cure of the aneurysm is certain. On these grounds recent surgical opinion is in favour of the operation. It is chiefly indicated in cases of traumatic aneurysm of young people. Before either proximal ligature or excision is undertaken, the circulation in the other carotid artery should be tested. A skilled surgeon could now restore the vessel with a graft after excision of the aneurysm.

5. *The Matas Operation*, i.e., obliteration of the sac by suture, leaving sufficient to transmit blood, may here find a field for usefulness, and, in favourable cases, exclude other forms of treatment.

Aneurysms of the External and Internal Carotid Arteries.—These are treated by ligature of the vessel below the aneurysm, or, if this be not possible, by ligature of the common carotid.

Aneurysm of the Innominate Artery.—Needling and electrolysis have both been used with success. The operation of choice, provided that both common carotids are pervious, is that of simultaneous ligature of the right common carotid and subclavian arteries. It has been followed by good results.

Aneurysm of the Subclavian Artery.

Of the 1st part.—The treatment is the same as that for innominate aneurysm.

Of the 2nd part.—After failure of medical treatment and of "needling," which should have a fair trial, simultaneous ligature of the common carotid and of the subclavian arteries beyond the aneurysm is indicated.

Of the 3rd part.—Direct compression and proximal compression have both been tried, and with some success. Proximal ligature of the first, second, or third part of the subclavian artery may be done; or ligature of the innominate and common carotid arteries; or amputation at the shoulder with high ligature of the artery. All of these operations have failed to cure the aneurysm, and the mortality has been appalling. Excision of the sac has given the best results. In a recent case of leaking subclavian aneurysm, I effected a cure by ligature of the innominate and common carotid arteries, surrounding the ligatured portions with a graft of fascia lata.

Aneurysm of the Vertebral Artery.—In the only reported case, the aneurysm occurred at the lower part of the artery, and the vertebral was tied close to the subclavian and divided. A cure resulted.

Arterio-venous Aneurysm of the Carotid and Jugular Vessels.—Digital compression of the carotid artery below the sac should be fairly tried first. Operative treatment is not to be lightly undertaken, both on account of its inherent danger and in view of the known natural history of these cases. In many of them the swelling remains stationary, and the disturbed cerebral and cephalic circulation ceases to cause the trouble it had originally produced. Severe pressure symptoms and rapid growth are the indications for operation. The artery and vein should be separated and the openings in each closed by suture, or the vessels are to be ligatured above and below the openings and the sac incised and emptied.

Subclavian Arterio-venous Aneurysm.—Treatment is the same as for the previous variety.

ABDOMINAL ANEURYSMS.

It is to be remembered that in dealing with these cases medical treatment ought first to be given a fair trial. In this connection it is of interest that two cases of cure after the administration of calcium chloride have been recorded.

Pressure on the vessel above the aneurysm may be applied by means of an abdominal tourniquet, and when the aneurysm is not too highly situated may prove successful. The pressure must not be applied for too long a stretch, but is to be repeated from time to time, a due watch being kept meanwhile over the patient's general condition.

Introduction of Wire into the Aneurysm has been the only other method of treatment attended by any success.

Steady diminution of the size of the entering artery by gradually tightened bands or ligatures of metal or of silk has been recently employed with some success; but in favourable cases surgeons, in the near future, will excise the aneurysm and restore the vessel by a graft.

Aneurysms of the Visceral Branches of the Aorta, with the exception of the renal artery, have not yet been brought into the domain of practical surgery.

Aneurysms of the Renal Artery have been successfully extirpated along with the kidney on more than one occasion.

The other vessels, in view of recent improvements in blood-vessel surgery, such as the Matas method of treatment for aneurysm, end-to-end or lateral anastomosis of vessels, and transplantation of vessel grafts, cannot fail to come under surgical treatment in the near future.

Inguinal Aneurysms.—The term is applied to aneurysms of the iliac arteries,

though the femoral may be involved. Digital pressure on the artery above may be tried first, and its action may be assisted by compression of the tumour. If pressure treatment fails after a fair but short trial, the Matas operation should be done, or the artery should be *ligatured* above the aneurysm. For ruptured aneurysm, and after failure of the above methods, the Matas operation or excision of the sac is called for.

Rutherford Morison.

ANEURYSM, THORACIC.—An intimate knowledge of the literature of this subject, together with practical experience of a large number of cases (amounting to several hundreds), compels me to confirm the general opinion that the results of the treatment of aneurysm are eminently unsatisfactory. Nevertheless there is much to be done, and all experienced in the matter will admit that the patient may be benefited in many ways by treatment. Proof of this position is to be found in the records of any large hospital where cases are frequent. Patients introduced into the wards suffering from pain, dyspnœa, distressing cough, etc., leave in a state of comparative comfort, to return in a few weeks, or perhaps months, in much the same condition as at first. Once more they obtain relief; and so the cycle continues, it may be, for several years. It would be a mistake to deny that even cure may occur, but this result is so rare as to be reckoned little more than a possibility.

TREATMENT.—This is directed to the relief of the symptoms, principally pain, dyspnœa, cough, and dysphagia; in securing this we aim also at the reduction in size of the sac, a thickening of its walls, and coagulation of the contents.

It must not be forgotten that some of the symptoms are not necessarily the direct result of the aneurysm, and may depend upon valvular lesion, heart-muscle weakness, or excessive blood-pressure—points that require our closest attention in selecting a plan of treatment. Fortunately, however, drugs and methods adapted to the relief of the aneurysmal symptoms are also suitable, at least in many instances, for treatment of the concomitant heart and circulatory conditions. Iodide of potassium, for example, is an excellent heart tonic; and we cannot do much better in reducing blood-pressure than insist upon rest, and a lowering diet.

Freedom from worry and excitement is in all cases highly important; but the fortunate fact that our patients are, as a rule, of a calm and cheerful disposition, though it simplifies in some ways the management of a case, renders it more difficult in others, inasmuch as a patient seldom realizes the gravity of the situation, and is often only with difficulty persuaded to obey instructions.

Rest.—It would perhaps be impossible to over-estimate the value of rest, but the questions will naturally arise, Should every case of aneurysm of the arch of the aorta be compelled to rest? And if exceptions be allowed, what are they?

Practically speaking, all cases are benefited by rest, but for some few absolute rest is perhaps not essential, this minority consisting of those whose only symptoms are nocturnal pain and consequent sleeplessness. These may be allowed to sit up, and may even take gentle exercise with advantage; but all alike must be impressed with the necessity of avoiding the exertion of sustained effort. In other words, it is highly important to restrict movements in all cases of thoracic aneurysm.

Diet.—The diet should be carefully selected both as to quantity and quality, and this even in cases in which it is not proposed to carry out the Tufnell plan of treatment. A mixed diet may be allowed, care being taken to avoid an excess of animal food; indeed, some patients are greatly benefited by a course of milk and farinaceous food alone, and this recommendation is offered notwithstanding the opinion held by many practitioners that the diet should be as dry as possible and highly nitrogenous.

In this connection it may be said that the treatment associated with the name of Tufnell, namely, starvation diet and absolute rest, is worth a trial in some cases, though the patient seldom submits to it for any length of time without protest, nor can it be urged that the results are encouraging enough to warrant coercion. The diet, as is well known, consists of a morning meal of 2 oz. bread-and-butter, with 2 oz. milk or cocoa; a meal at mid-day of 3 or 4 oz. meat, with 2 or 3 oz. potatoes or bread and 3 or 4 oz. water; and an evening meal of 2 oz. bread-and-butter and 2 oz. milk or tea. Some cases do badly under this plan, and care must be taken to select suitable ones, for the broken-down syphilitic patient, or the man with aortic regurgitation and failing compensation, should not be subjected to the risk. A modified Tufnell diet, however, in conjunction with rest and iodide of potassium, constitutes the plan of treatment on which our best reliance is to be placed.

Drugs.—The most useful drug in the treatment of aneurysm is undoubtedly iodide of potassium, which is generally supposed to have been first employed for this purpose by Bouillaud. In conjunction with rest and diet, it leaves little to be desired as a means of relieving pain. It relieves all varieties of the pain associated with aneurysm, but especially for the true aneurysmal pain which is worse at night and is relieved by change of posture it is almost a specific. The dose should be large, but 15 to 20 gr. three or four times a day is generally sufficient, though in some cases relief is obtained only by the use of a considerably larger daily amount, and some authorities recommend as much as 1 dr. for a dose. Occasionally the pulse is accelerated by the use of iodide, but this is of little importance, and does not interfere with the beneficial action of the remedy.

As a rule a few days elapse before any improvement is noticeable, and some patients are unable to bear the necessary dose. When this happens it is well to withdraw the iodide of potassium and substitute the strontium salt in its place. It is unnecessary here to discuss the action of this salt further than to say that it seems to relieve pain, lower blood-pressure, act favourably on heart muscle, aid formation of clot, reduce the size of the sac, and thicken its walls.

The treatment should be persevered in for six or eight weeks at a time, and rest and diet certainly increase the usefulness of the remedy.

Notwithstanding the close connection between syphilis and thoracic aneurysm, it would not be advisable to employ salvarsan, even in cases in which a positive Wassermann reaction has been obtained.

Operative Measures.—The results of distal ligation in the treatment of aortic aneurysm have not been encouraging, though the cases recorded by Heath, Barwell, and others, as treated by this method, would seem to suggest that we are not justified in excluding our surgical friends from some say in the matter.

Extreme dyspnoea, amounting at times to threatened suffocation, generally associated with congestion and blueness of the head and neck, may be benefited by venesection; and chloroform has often given relief. The operation of laryngotomy is intensely disappointing in its results, for the simple reason that the obstruction is generally below the larynx and rarely due to bilateral abductor paralysis. In two cases, when death seemed imminent from suffocation, and tracheotomy was performed without relief, as the trachea was compressed at the bifurcation, the threatened danger was averted by inhalation of nitrite of amyl; but the relief was, of course, only temporary.

Electrolysis.—Galvano-puncture or electrolysis was recommended many years ago for the treatment of thoracic aneurysm. It consists of the introduction into the sac of two insulated needles, bare at the points, by which means a galvanic current is passed through its contents. The object of this proceeding is, of course, to induce coagulation of the blood in the sac about the positive

needle, and care must be taken that the points are not allowed to touch. Indeed, it would seem to be unnecessary to introduce more than the needle connected with the positive pole, for the circuit can be closed by the application of the negative pole through the medium of a large surface rheophore to the skin close to the sac. In the few cases I have treated by galvano-puncture the results were not satisfactory enough to encourage further attempts, and this would seem to accord with the general experience. A reference to the literature of this part of the subject will, I think, convince the reader that most of the cases in which benefit has been claimed from this plan of treatment would probably have done as well with some other less heroic means; and in not a few it has hastened a fatal termination.

Another form of treatment having the same object, and associated with the names of Moore and Loreta, is the introduction into the sac of foreign material, such as wire, silk, horsehair, or catgut. Personally, I have no experience of this plan, and am not favourably impressed by the published results. The electrolytic method in conjunction with the introduction of fine iron or gold wire has also been tried, and in a few cases successful results have been claimed.

Internal Irritation of the Walls.—In 1890 Macewen advocated a plan for inducing the formation of white thrombi in the sac of an aneurysm by irritating the internal surface with the point of a needle. I subjoin Macewen's description of his method: "Before performing the operation the skin over the aneurysm ought to be carefully cleansed and rendered aseptic. The aseptic pin ought then to penetrate the sac and pass through its cavity, until it comes in contact with the opposite side. It ought to touch and no more. Then one of two methods may be employed: either to move the pin over the surface of the inner wall so as to irritate its surface, or to allow the impulse of the blood-current playing on the very thin pin to effect the same object. If the wall penetrated by the pin on introduction be dense, the former method will be preferable, as the force of the blood-current produces such a feeble action on the thin pin as to be insufficient to move it to and fro whilst it is firmly grasped by the dense wall. After acting thus for ten minutes at one part, the point of the pin, without being removed from the sac, ought to be shifted to another spot, and so on until the greater portion of the internal surface opposite the point of entrance has been touched; this ought to be done in a methodical manner. A single insertion of the pin through the aneurysmal sac into its interior may be sufficient to enable the point of the instrument to come into contact with the greater part of its internal surface, but in some cases puncture from various sides of the external wall may be necessary so as to reach portions of the tumour which cannot be attacked from the first puncture" (*Lancet*, Nov. 22, 1890). The period for which the pin has been kept in the sac has varied between a few minutes and many hours, but forty-eight hours is given as the limit of safety.

Only a limited trial has apparently been made of this plan of treatment in cases of thoracic aneurysm, and I confess I have been deterred by the fear of displacing clot that might already line the sac. All practical physicians recognize also the enormous difficulty presented at times in distinguishing between sacculated and fusiform aneurysms.

A somewhat similar procedure was introduced in Paris in 1888, when Dr. Constantin Paul advocated the introduction of a number of long and very fine needles into the sac, to be left there for a few minutes with a view to setting up a slight degree of adhesive inflammation—the operation to be repeated in a few days at another part of the sac. Paul contended that this results in thickening of the walls, and possibly this plan would commend itself to some in preference to Macewen's; but it is obvious that both are more suitable for aneurysms of smaller vessels than for those of the aorta.

Injection of Gelatin.—Based upon the observations of Dastre in 1895, that the injection of a solution of gelatin into the veins of a dog favoured coagulation of the blood, Lancereaux proposed the employment of a similar solution in the treatment of aneurysm. Since then many cases have been treated by gelatin injection, and some with surprising results. In his earlier cases, Lancereaux employed a 2 per cent sterilized solution of purified white gelatin, of which he used 4 or 5 oz. (introducing the needle deeply into the subcutaneous structures, buttock, axilla, etc.); but later he reduced the strength to 1 per cent, and advocated the injection of 9 or 10 oz. of the solution, repeating the operation every three or four days until eighteen or twenty injections were made. In some of my own cases I have employed as strong a solution as 4 per cent, of which 1 oz. or rather more was injected, and repeated every three or four days according to the state of the patient; but the weaker solution is probably safer, and seems to do as well.

This plan of treatment appears to be most useful in cases in which a false sac has become established outside the bony structure of the chest, with threatened perforation; but it is evident that the treatment must be subjected to a much more extended trial at the hands of skilled observers, and under conditions free from risk, before a definite decision can be arrived at as to its general utility. Undoubtedly in some cases the injection of a gelatin solution does induce coagulation of the blood in the sac. In one very striking case of my own there was a pulsating sac the size of a large orange, pointing to right of sternum above the fourth ribs, and covered by shining skin of purple colour. Five injections were made into axillæ and beneath adjacent pectoral muscles at intervals of two or three days; after the first, a distinct change was noticed in the contents of the sac; after the fifth it ceased to pulsate, and became as hard as a cricket ball, being also reduced in size. But another of my patients developed tetanus after the ninth injection, which was the more unfortunate as otherwise the case seemed to be doing well.

In fact it should be recognized that in this agent we clearly have a remedy that is powerful for good or evil. It may perhaps come to be regarded as a medicinal factor in the treatment of aneurysm, second only in importance to iodide of potassium; but at present the gelatin treatment is attended by considerable risk, and very few practitioners who have given the plan an extended trial have succeeded in avoiding some untoward result. The chief danger seems to lie in the fact that commercial gelatin is apt to contain the tetanus bacillus, and the difficulties in sterilizing the solution are very great, as the properties of gelatin are destroyed when the temperature is raised beyond a certain point. It is hoped, however, that this difficulty may soon be overcome, so that the treatment may be undertaken in suitable cases without undue risk to the patient.

Narcotics.—When pain defies rest, diet, and iodide of potassium, it may be relieved by morphia; and without doubt the hypodermic syringe is the best method for its administration.

The troublesome symptom of irritating cough may, in some cases, be aggravated by iodide on account of its tendency to increase bronchial secretion. These are nearly always cases of aneurysm of the transverse arch, in which the sac presses upon the lower part of the trachea. As a rule the iodide, with rest, will give relief by reducing pressure; but where the sac is intimately incorporated with the trachea, and the secretion is copious and expelled with difficulty, the drug may fail. Here small doses of morphia, with soothing inhalations such as menthol, conium, or Friar's balsam, may afford relief; but the administration of the sedative must be watched with care on account of the respiratory difficulty.

David Drummond.

ANGEIOMATA.—These tumours require treatment when (1) They are obvious disfigurements; (2) They are increasing in size; (3) They have become inflamed or ulcerated, with the associated risk of hæmorrhage. If a nævus is small, is not upon an exposed area of the body, and is not increasing in size, no treatment is required. Some of them disappear spontaneously.

The aim of all treatment is to remove them so as to leave only the slightest trace of their former presence, and this is best attained by means of excision. In most instances this can be done. In certain situations, such as the scalp, it is imperative, since destruction of the nævus *in situ* without removal will leave an area that will always be devoid of hair. The simplest procedure is to enclose a fusiform area in which the nævus is situated by two incisions, which must be just free from the margin of the tumour all round. One apex of the enclosed area is seized by toothed forceps, and the tumour can then be peeled off rapidly by traction, aided by a few touches of a scalpel. By this means the free hæmorrhage that is frequently regarded as the necessary accompaniment to the removal of a nævus is almost entirely avoided—a consideration of the utmost importance when such a tumour requires removal from the scalp of an infant.

This procedure must be modified for the treatment of nævi occurring in certain situations such as the orbit, the nose and mouth, the lips, the external genitalia, and the circum-anal region. A nævus in the orbit which has given rise to proptosis must be removed by piecemeal dissection with two pairs of dissecting forceps through an incision in the eyelid. By this method all injury to the rest of the structures in the orbit is avoided, since the nævus tissue shells out easily. A combination of methods must be employed for the removal of a large cavernous nævus from the lips, which frequently appear as large pendulous shapeless masses. Make a small vertical incision into the lip, and through the opening thrust the fine needles of a galvano-cautery into the centre of the tumour. The needles must not be heated until they have been introduced; otherwise the edges of the incision will be charred. Having burnt away some of the nævoid tissue, allow the needles to cool, and then withdraw them. Stitch up the incision with fine silkworm-gut sutures. By a frequent repetition of these measures the whole of the nævus can be destroyed with very slight disfigurement to the lip. If the growth encroaches upon the surface of the gums, palate, or mucous membrane of the nose, the free edge must be immediately destroyed by cauterization to prevent its spreading to regions inaccessible to treatment. For a nævus in the genitalia or circum-anal region, a combination method of excision and cautery or electrolysis is the most valuable. Nævi in the region of the parotid gland often grow to a formidable size, and their removal may be complicated by the branches of the facial nerve running through them. The skin over the whole tumour should be turned forwards as a flap by a curvilinear incision in the region of the angle of the jaw. When the tumour has thus been exposed it is removed by blunt dissection with dissecting forceps. The nævus is seized in the forceps and removed piecemeal by gentle tearing, the direction of the tear always being made along the lines of the branches of the facial nerve. The latter are thus easily exposed, and permanent injury is only likely to result to them from careless or too forcible tearing. When the piecemeal dissection has been properly carried out, any slight facial weakness from the stretching of the nerve fibres that may sometimes ensue is of a purely temporary character and undergoes a rapid spontaneous recovery.

When, from consideration of the situation and size of the nævus, excision or any of the foregoing combined methods appear to be impracticable, other means of treatment must be adopted. The essential process underlying these other methods is the production of necrosis of the nævoid tissue. A large number have been devised, but only three of them can be considered of real value—

cauterization, electrolysis, and freezing by carbon dioxide snow. Cauterization is the more rapid way; electrolysis and CO_2 snow leave less ultimate scarring. The two first-named processes can be carried out by means of fine needles attached through a resistance board either to a main or to a storage battery. For electrolysis a current of 10 to 20 ma. is sufficient and safe. Either the negative or positive needle, or both, may be inserted into the tumour. The negative needle has the advantage of destroying the tissue more rapidly than the positive, and the evolution of hydrogen can be used to gauge the amount of destruction that has been done at each operation. There is no such indication when the positive pole is used, and although this is said to yield a firmer thrombus, it has the additional disadvantage of staining the tissues brown by a deposit of iron from the needle. Blanching of the tissues by hydrogen must not be induced to an extent likely to cause sloughing at the surface, since a deep permanent scar will be the result. For fine capillary nævi on the face, a few pricks by the negative pole are generally sufficient to avoid all disfigurement. CO_2 snow has no specific or selective action upon angiomatous tissue, but by producing a "frost-bite," leading to sloughing, the mass is destroyed. The residual scarring is very slight, and the method is of great value where the resulting disfigurement is in an always visible position. It is used as follows: Liquid CO_2 is allowed to escape from the storage cylinder with such rapidity that it immediately solidifies. The crumbling snowy mass is collected in a cone of "wash-leather," and thence transferred to a hollow metal rod. A wooden stick is then thrust into the rod, and with the latter resting upon a table by one end, the contained snow is welded into a firm mass by blows of a hammer upon the end of the stick. The snow is then extruded in a condition fit for use. It is applied to the surface of the nævus for a varying length of time—from 5 to 30 seconds—and with a varying pressure, according to the thickness of the tumour. The frozen surface is then protected by a dressing of bismuth ointment spread upon sterilized gauze, until healing is completed. For a large nævus the process may have to be repeated several times. An anæsthetic is advisable for a long exposure with deep pressure, as there is considerable pain at the time of application. (See also CARBONIC ACID SNOW, TREATMENT BY.)

When a nævus has been destroyed by these methods and the resulting fibrous tissue has been allowed to shrink, a further improvement can frequently be effected by excision of the fibrous mass. It is hardly necessary to add that all these operations must be carried out under conditions of the most scrupulous surgical cleanliness. (See also ELECTROTHERAPEUTICS.) *George E. Waugh.*

ANGEIONEUROTIC OEDEMA.—(See URTICARIA.)

ANGINA LUDOVICI.—In this condition the infection may, in some cases, spread from the deep cervical lymphatic glands, probably gaining entrance through the tonsils. In other cases the floor of the mouth or tongue may be the site of infection. In any case the infection spreads from the submaxillary region into the deeper tissues of the neck and into the submucous tissues of the mouth, tending to spread from this latter area to the epiglottis and larynx.

The majority of the subjects are stout and apparently healthy males, those of an alcoholic tendency and a short thick neck being more commonly affected. If relief be not gained shortly there is great danger of death from respiratory obstruction. Even if the danger of laryngeal obstruction be overcome, the patient may pass into a profound septic condition and ultimately die in an asthenic state.

TREATMENT.—It is essential to make multiple incisions into the area of

cellulitis, but owing to the presence of œdema of the fauces, the administration of an anæsthetic is associated with considerable risk. Under certain circumstances the patient's condition is so bad that any form of anæsthetic can be dispensed with. In less advanced cases a local anæsthetic is preferable, but should a general anæsthetic be decided upon, chloroform alone should be administered. Free incisions are made through the skin and subcutaneous tissue, and if there is any evidence that the condition has spread from a gland, the deep fascia must also be opened. These incisions generally bleed freely, but as a rule no pus is obtained. The deeper tissues may be opened up more freely by means of a pair of sinus-forceps, and it may be necessary to control the hæmorrhage by plugging the wound with gauze. Fomentations should then be applied. In the earlier stages but little lymph flows from the incisions. Sir Almroth Wright has shown that this is due to the fact that the lymph is coagulated. He therefore advises the administration of large doses of potassium citrate, and the dressing of the wound with a hypertonic solution of 4 per cent of sodium chloride and 1 per cent of sodium citrate in water. From the beginning, a close observation must be kept for the onset of dyspnœa. It may be possible in a few cases to prevent the increase of this by making incisions into the tongue and floor of the mouth. Owing to the difficulty of opening the mouth it is, however, an unsatisfactory form of treatment. For the same reason it is often difficult, if dyspnœa be actually present, to perform intubation of the larynx, and therefore it is often requisite to perform tracheotomy. This operation should be performed above the isthmus of the thyroid, and owing to the amount of swelling of the subcutaneous tissues, it is not infrequently an operation of considerable difficulty. Should the patient survive the first few days, the discharge from the incisions will become more abundant and more definitely purulent. With the onset of these changes, if the patient's general condition remains good, the amount of swelling will rapidly decrease. Later, however, large portions of the subcutaneous incisions may be extruded in the form of sloughs, and convalescence thereby be much prolonged. Throughout the course of the disease the patient's general condition must be supported by stimulants, strengthening foods, and tonics. Wherever possible, a vaccine should be prepared at an early date, so that treatment by inoculation can be commenced without delay.

Albert J. Walton.

ANGINA PECTORIS.—Treatment may be divided into two parts: (1) The direct treatment of the paroxysms; and (2) Treatment in the interparoxysmal periods.

In the great majority of cases that prove directly fatal, angina pectoris is known to be associated with disease in one form or another of the coronary arteries. The disease, however, regarding it as a clinical entity, may be met with apart from any lesion of the coronaries: so much must be admitted. In rare cases of mitral stenosis it is thus met with; death in these cases does not result from the angina (in the writer's experience), but from the ordinary disturbance of the circulation wrought by the valve lesion. Moreover, in the disease associated with coronary changes, it sometimes happens that the angina pectoris subsides, while the symptoms and signs of cardiac muscle failure develop, and run their ordinary course to a lethal termination. Many cases of angina pectoris, *but not all*, are associated, moreover, with habitual high, or fairly high-arterial tension. This condition becomes intensified during the paroxysm: whether as cause or effect has been matter of controversy. It is found that remedies which dilate the arterioles, and so lower blood-pressure, at the same time relieve the pain of angina. It is not necessary, however, that the blood-pressure should be high in order that the paroxysm may be relieved by

vasodilators—probably the condition of the heart and the relationship of its contractile power to the burden imposed on it have to be considered in such cases, and vasodilators will still lighten the burden of the heart in the presence of quite low tension. However this may be, the *trial* of vasodilators must not be limited to cases associated with high arterial tension.

1. Treatment of the Paroxysms.—It is usual to begin the treatment of the paroxysm with the inhalation of nitrite of amyl, and such inhalation often gives an indication of the effects likely to be obtained from the vasodilator class of drugs. It is best to give the patient, who is found to obtain relief from amyl inhalation, a box of small glass phials containing the drug, each wrapped up in linen. When he feels the onset of an attack he takes out one of these so-called “capsules,” breaks it between his finger and thumb, and holds it to his nostrils for inhalation. The “capsule” may be held in a handkerchief, so that nothing unusual is observed by bystanders, should it be necessary to apply the remedy in public.

A considerable number of nitrites are in use for internal and more or less regular use : liq. ethyl nitritis, sodii nitris, spiritus glycerylis nitratis or trinitrini or glonoini, or tabellæ nitroglycerini (chocolate excipient), or tabloids of erythrol-tetranitrate. Erythroltetranitrate is believed to keep up its effects for a longer time than do the others, and tabloids are made containing respectively three strengths : $\frac{1}{4}$, $\frac{1}{2}$, and 1 gr. Even in the case of the last the difficulty of maintaining the action of the drug is great. It is often advisable to anticipate paroxysms that occur in the night by giving a full dose of a vasodilator at bedtime. Alcohol is essentially a vasodilator, and its good effects in the paroxysm of angina pectoris were long ago recognized. A glass, or less, of whisky or brandy taken in hot water at bedtime, will often ward off a nocturnal seizure.

Diffusible stimulants, diluted for immediate use in camphor water or the like—spts. ammon. arom.; spts. ætheris; spts. chloroformi, etc.—singly or in combination, are generally useful in the paroxysm, and often promote that much desired effect, the eructation of “wind,” which seems often to end the attack, whether the result be *propter hoc* or merely as is probable *post hoc*.

In the classic case of Dr. Arnold, of Rugby, it is related that Dr. Bucknill gave brandy and laudanum to the patient, and a better combination at the time could hardly be devised—the brandy as a vasodilator, the laudanum as an anodyne. To-day, with a deeper—if still imperfect—insight into the disease, we give nitrites in place of alcohol, and a hypodermic injection of morphine in place of laudanum by the mouth. Moreover, in order to mitigate the disagreeable after-effects of morphine that occur in many subjects, we combine the drug with atropine, which, like strychnine, is a respiratory stimulant. Hypodermic injection of morphine by the attendant is an immense improvement, inasmuch as it obviates the possible tendency to too frequent resort to the remedy by the patient himself, and the stomach and intestines are very much less disturbed by it than they are when opium in any form is taken by the mouth. There are some patients, however, who suffer from severe sickness and inability to take nourishment after morphine has been given even hypodermically, and guarded, as it were, by atropine. Fortunately, such cases are very rare, for their treatment is one of the greatest difficulty when nitrites fail to relieve, and, indeed, nitrites seldom continue to effect complete relief to the end of a case. No general rule can be given, but by experiment—altering the proportion of atropine and diminishing the morphine—a dose of the two alkaloids may be arrived at that will give great relief without the production of sickness. In all cases of the disease, when it becomes necessary to give morphine, the dose should be very small at first, and it is the invariable practice of the writer to combine it with atropine. It is easy and safe to increase the dose gradually, when once

the individual tolerance of the drug is known. To give even $\frac{1}{4}$ gr. of morphine without any knowledge of the idiosyncrasy of the patient, and especially without knowing whether or not he is the subject of seriously diseased kidneys, is always a risk. Much bronchitis, again, with a tendency to accumulation of secretion in the tubes, is quite as strong a contra-indication as regards the use of morphine as is Bright's disease. Beginning with infinitesimal doses, and combining the morphine with atropine, it is usually possible so to administer the drug that its beneficial effects are exerted without safety being compromised.

Very exceptionally it may be necessary to have resort to the inhalation of chloroform, and there is good evidence of the occasional value of the treatment. When morphine has already been given with only partial success, inhalation of a very small quantity of chloroform may accomplish complete relief for a considerable period, promoting the action of the morphine.

2. Treatment in the Inter-paroxysmal Periods.—It is all important, in the first place, that the patient should lead a regular, quiet life, and that he should especially avoid circumstances likely to expose him to *physical exertion* and *mental emotion*. The rush up a short stair to catch a train at a railway station, the transient loss of his temper, may cost him his life. Walking against a strong and cold wind is peculiarly apt to bring on a seizure.

The dietary of the subject of angina pectoris perhaps comes next in importance to tranquillity of life. The evil effects of tympanitic distention of the abdomen cannot be denied; it is admitted by nearly all sufferers from the disease. It is known that starchy food is the great promoter of tympanites, and practical experience and experiment will soon convince any one of the fact. Flesh-food, again, favours the contractile vigour of the heart-muscle along with the musculature of the body generally, and the heart-muscle is apt to be ill-nourished in the disease. No fear need be entertained, on the one hand, that excess of flesh-food will induce "excess of uric acid" and all that faulty metabolism which such a state connotes, *provided carbohydrates are at the same time cut down to a minimum*. The writer, on the other hand, has no fear of letting the patient have with his flesh-food, which taken alone seems to lack the property of affording the feeling of repletion, *green* vegetables, thoroughly cooked, and best squeezed through a sieve. These aid in the maintenance of free action of the bowels, an important detail of treatment. No doubt satiety and lethargy are experienced by the carnivora after feeding, but they, as a rule, have one meal in twenty-four hours, which thus must be a large one. Let the reader, however, contrast the belly development of the lithe carnivora with that of the slow, though it may be powerful, herbivora. Though any large quantity of fat in the diet of the subject of angina pectoris is to be deprecated, it is probable that the patient whose carbohydrate food is cut down to a minimum may be allowed a fair amount thereof, should his inclination lie in that direction. To simplify the digestive processes, the writer recommends that breakfast should be made the bread or carbohydrate meal of the day. The bread is best taken in the form of thin crisp toast, buttered cold, its crispness promoting mastication and thorough mixing with saliva. *China* tea should be used, or weak coffee; cream may be allowed therewith. Fruit is probably best taken with or after breakfast, and its inclusion in the dietary is wholly beneficial in most cases. The mid-day meal should consist of some sort of flesh-food plainly cooked, with green vegetables, as already recommended. One kind or another of green vegetable is to be obtained all the year round, but occasionally such a vegetable as turnip (with 5 per cent of carbohydrate in the form of pectose) may be allowed, for the patient after a time longs for an occasional change. Carrots, on the other hand, cannot be allowed, owing to the large amount of carbohydrate they contain (10 per cent of sugar).

The evening meal, again, may be begun with a *small* quantity of *consommé*—for such promotes digestion—but no rich heavy soup on any account. Flesh-food follows, and fish, joint, or bird may be allowed. No large number of courses, however, is to be recommended. Custard, or junket and cream, should be permitted only when *one* flesh-course has been taken. The less fluid drunk with the meal the better, and on no account should large draughts be taken. It is the writer's experience that when carbohydrates are reduced to a minimum, patients have no desire to drink much.

For the sufferer from angina pectoris, it is certainly important to rest after a meal. Great risk may be incurred by neglect of this rule, and this risk is greater if the meal has been a "mixed" one, like the luncheon and dinner of ordinary society. In the case of the poor, no less care must be taken with regard to the dietary, and the difficulties to be overcome are much greater; but with a knowledge of the composition and price of different food-stuffs they can be overcome. Excessive bread-eating, inasmuch as bread is a cheap food, offers the greatest difficulty in the case of the poor: on the other hand, the small quantity of flesh-food usually obtained by them is perhaps a saving fact under the circumstances.

The *Medicinal Treatment during the Inter-paroxysmal Period* should be directed against constipation, dyspepsia (essentially treated by dietetics), insomnia, and other disorders calculated to promote a seizure of angina. An excellent mixture for the relief of constipation and dyspepsia is 20 gr. of compound rhubarb powder suspended in an ounce of peppermint water and taken three times daily. Ten grains may suffice for the dose. As regards pure insomnia, chloral is often useful, unless there be great feebleness of the heart. It acts on the arterioles as a vasodilator, but also as a depressor of the vigour of the heart-muscle. Chloral formamide is safer, and whenever there is an element of dyspnoea or threatening of angina associated with the insomnia, a hypodermic injection of morphine and atropine is best. Arsenic has long been in use in the treatment of angina pectoris. It is usefully given in the form of liq. acidi arsenosi, combined with liq. strychninae, 1 per cent, 4 or 5 min. of each in $\frac{1}{2}$ or 1 oz. of water taken after meals. When there is any tendency to nocturnal attacks, a tabloid of erythrol-tetranitrate, $\frac{1}{2}$ or 1 gr., may be taken each night at bedtime in anticipation of an attack.

Iodide of potassium is often recommended in arterial degeneration, but probably to be efficient the drug must be employed earlier than is usually the case. While the writer has perhaps too low an estimate of the value of the drug, a course of it is always safe, and may prove beneficial between the paroxysms of angina pectoris. Its tendency is to lower arterial tension. Its use might seem specially indicated in cases of syphilitic aortitis associated with angina pectoris and narrowing of the coronary orifices. The writer has repeatedly used it in such cases, but has never witnessed what may be termed a "specific" result. As far as the relief or removal of symptoms goes, he has never seen any result approaching in success that commonly witnessed from the administration of the drug in cases of intrathoracic aneurysm. It seems almost idle to expect that a narrowed coronary orifice or artery will be again reopened to its normal size or anything approaching it. The removal of a gummatous neoplasm is the most that can be hoped for.

Graham Steel

ANKYLOSIS OF JOINTS.—The causes of ankylosis may be extra-articular (false ankylosis), or within the joint (true ankylosis).

False ankylosis may be due to: (1) Peri-articular adhesion; (2) Spasm of muscles from disease in the joint, or from hysteria; (3) Myositis ossificans.

True ankylosis may be either fibrous or bony.

True fibrous ankylosis may be due to : (1) Acute suppuration ; (2) Infection with various organisms, e.g., gonorrhœa, tubercle, influenza, rheumatism ; (3) Trauma. Fibrous ankylosis is sometimes divided clinically into sound and unsound ; the terms indicating whether the cause of the stiffness is quiescent or not.

True bony ankylosis may be due to : (1) Suppuration in the joint, with destruction of cartilage ; (2) Acute infection, with no suppuration.

Peripheral bony ankylosis is the description given to stiffness due to interlocking of osteophytes in osteo-arthritis.

Congenital ankylosis is also met with. The commonest example is at the upper radio-ulnar joint. The ankylosis is bony, usually bilateral, there is no secondary wasting of muscles, and the upper end of the radius can be excised with no fear that the operation will produce deficient growth in the radius. A flap of fascia may be interposed to prevent reunion ; but the results of operative treatment on these lines are disappointing, owing to a constant curve of the radius preventing full supination.

True congenital ankylosis of the shoulder is rare, the limitation of movement at this joint in a child usually being due to either congenital elevation of the scapula or to the after-results of a neglected Erb's palsy.

Other joints may be stiff from intra-uterine epiphysitis, or from infection at a very early age with the pneumococcus or gonococcus.

DIAGNOSIS.—The joint being stiff, every care should be used in attempting movement, the dangers being : (1) A fresh outbreak of inflammation ; (2) Dislocation, some shortened ligament acting as a fulcrum ; (3) Injury to large vessels and nerves which have become structurally shortened in the concavity of a flexed joint ; (4) Fracture of a bone near the joint, these bones being nearly always atrophied, and more likely to give rise to fat embolism.

In bony ankylosis there is no movement and no pain, points of great value in separating it from a fibrous ankylosis.

Differential diagnosis is especially difficult in the shoulder, where a bony ankylosis may be diagnosed as fibrous owing to the free mobility of the scapula. In the hip, a fibrous ankylosis may be diagnosed as bony, because the joint is surrounded by strong thick muscles. Before proceeding to treatment, every ankylosed joint should be x-rayed, and then the ankylosis determined. If there still be doubt, examination under an anæsthetic may reveal slight movement. In fibrous ankylosis there is movement, however little, and usually it produces some pain.

It is important to distinguish true ankylosis from false ankylosis due to peri-articular adhesions. The points in favour of the latter are : (1) The history is short, and one of trauma or of slight inflammation ; (2) Movement is limited, it is true, but within these limits there is no stiffness or crepitus ; (3) With gentle manipulation under an anæsthetic, the adhesions can be felt to snap, and at once free movement is possible. The sensation is quite different from the gradual and continuous grating sensation given to the hand of the operator as intra-articular adhesions are broken down.

In true fibrous ankylosis it is difficult to estimate the condition. There may be : (1) Thickening of the capsule ; (2) Adhesions of the capsule and synovial membrane in folds or recesses ; (3) Bands in the joint ; (4) Fibrous tissue between the bone ends.

Points in favour of an extensive involvement are : (1) The history is long, and of subacute or acute inflammation ; (2) Under an anæsthetic the limitation of movement is rigid.

Myositis ossificans should be suspected as a cause of stiffness after injury, especially in the case of the knee and elbow-joints.

TREATMENT.—This may be considered under the headings of: (1) Prevention; (2) The treatment of fibrous ankylosis; (3) The treatment of bony ankylosis.

1. **Prevention.**—The treatment differs according as the joint inflammation is: (a) Tuberculous; (b) Traumatic; (c) Due to infection with an organism other than tubercle.

a. *Tuberculous.*—The most reliable proof that the inflammation in a joint is due to the tubercle bacillus is a positive complement-fixation reaction.

To prevent ankylosis the best treatment is:—

i. Reduce the deformity by extension in the line thereof. The object of extension is to relax the muscles which were in spasm. It must be in the line of the deformity (*Fig. 1*). If pain recurs after being temporarily relieved by extension, the most likely cause is that the extension is now too great, the pull coming direct on the capsule of the joint now that the muscle spasm has passed off.

Fig. 1.—Method of straightening an inflamed tuberculous knee. One extension pulls in the line of the tibia, a second pulls the leg forward, a third pulls the femur backward.

ii. Having got the joint into the most serviceable position, fix it for twelve months after all pain has disappeared. The rigid fixation of the joint prevents ankylosis, because ultimate ankylosis in a tuberculous joint is due to fibrous tissue. The fibrous tissue is preceded by granulation tissue; the best method, therefore, of preventing the formation of fibrous tissue is by rigid fixation to allay the inflammation and consequent formation of granulation tissue.

iii. Systemic treatment—e.g., sunshine, cod-liver oil, tuberculin.

b. *Traumatic.*—To prevent ankylosis, start massage and passive movements early. The test that the joint is progressing satisfactorily is that there must be a daily increase in the amount of passive movement possible.

c. *Infective.*—Every attempt must be made to find the primary focus of infection and remove it, the treatment being supplemented by vaccines. In addition to this, for acutely-inflamed infective joints—e.g., due to the gonococcus, staphylococcus, etc.—what is known as the Murphy treatment gives excellent results. The essentials of the treatment are:—

i. Injection into the joint of 2 per cent formalin in glycerin. The formalin injection produces a polymorpholeucocytosis, not only in the joint but also systemically, and so prepares for resistance against the invasion of the

organism. Turpentine is more efficacious in producing such a leucocytosis, but practically we cannot get a solution of turpentine (Venice), or a suspension, in such minute particles as to avoid the risk of phlyctenular necroses in the synovial membrane. The risk is present even with 2 per cent formalin in glycerin, but if the "solution" be over twenty-four hours old, there is no real risk of this. The mixture is thick, and has to be inserted with a special pressure-screw syringe. The immediate result is an increase of pain and swelling in the joint for twenty-four hours. At the end of forty-eight hours the patient is relieved of his pain. The injection is repeated at the end of a week, and, a week later, movements are commenced.

ii. Extension. In the intervals of the above, powerful extension is kept up on the joint.

2. Treatment of Fibrous Ankylosis.—If the adhesions are extra-articular, excellent results can be obtained by movement under an anæsthetic—so breaking down the adhesions—supplemented by early massage, and active and passive movement.

If the adhesions are intra-articular, no treatment is advisable in the way of breaking them down or stretching them, unless the joint is quite cool. In other words, the ankylosis must be clinically sound.

If the adhesions have followed an infective arthritis the primary focus of which has not been removed, this latter must still be done.

In the treatment of fibrous ankylosis following trauma, or infection which is non-tuberculous, I have found it of very little value to attempt breaking down adhesions under an anæsthetic. The ultimate results may be a joint more fixed than before, apart from the risks of forcible movement described above. Forcible movement to place the limb in a more serviceable position is, of course, subject to the same risks, but in non-tuberculous cases it is justifiable. Personally, I prefer to do either an osteotomy close to the joint or an arthroplasty, using a flap of fascia and fat to prevent reunion of the bones. I have never seen any benefit from fibrolysin or from cataphoresis with chlorine ions, unless these two treatments were supplemented by massage and passive movement. Although, in my opinion, the sudden correction of deformity is justifiable, the risks are

Fig. 2.—Type of apparatus used to straighten a fibrous ankylosis of the knee following tuberculosis.

certainly great. I therefore suggest, as an alternative, either osteotomy, arthroplasty, or gradual extension.

The gradual extension may be applied in bed on the same principles as in the correction of early deformities; or it may be applied in a Hessing's apparatus, leather casings being moulded accurately to the limb above and below the joint, and these connected by elastic or spring traction (Fig. 2). If on examination under an anæsthetic the adhesions are apparently slight, massage and passive movements will produce a comparatively movable joint; but I am sure that it is unwise to attempt repeated manipulations under an anæsthetic if the adhesions are at all strong.

If the intra-articular adhesions have formed in an old tuberculous joint, the patient, in the present state of our knowledge, must be content to remain

with a stiff joint. We can improve its position by gradual extension (*Fig. 2*) or by osteotomy, but an arthroplasty is not recommended; and, as far as we can judge, the danger of lighting old tuberculous mischief by forcible movement is greater than the disability of the average stiff joint.

3. Treatment of Bony Ankylosis.—Here, again, we must be sure that the ankylosis is sound. If sinuses are present, any dead bone must be removed, and the sinuses must be induced to heal by scraping, vaccination, etc. The treatment of a sound bony ankylosis depends partly on the joint and partly on its position—e.g., an ankylosed hip in a young person is compensated by an increased mobility of the lumbar spine; but an elbow ankylosed in an extended position, or an ankylosis of the temporomaxillary joint, is a severe disability, and must be remedied.

In the case of bony ankylosis of one elbow, the temporomaxillary joint, or both hips, the best treatment is an arthroplasty, performed by reshaping the bone ends, and interposing between them either a flap of fascia and fat, or a piece of Baer's membrane (sterilized, chromicized pig's bladder).

If one hip be ankylosed in a position giving apparent shortening, the best treatment is a subtrochanteric osteotomy, division of the adductor longus tendon close to the pubic spine, and a plaster casing, applied with the thigh in a slightly abducted position.

In the case of the shoulder, the average patient would be wise to leave it as it is. An increased range of abduction may be secured by an osteotomy at the upper end of the humerus and fixation in an abducted position. When union occurs, the elbow will be carried at the side by the angle of the scapula being pushed to the middle line. When the patient rotates the scapula forwards by the serratus magnus, the arm will be abducted through an angle of almost 90°.

In a bony ankylosis of the knee, due to the patella being tethered to the femur, arthroplasty to that extent is justifiable; but if there be bony ankylosis between the femur and tibia, the best treatment is simply to correct deformity. In adults this is done by cuneiform osteotomy; in children it is done by curvilinear osteotomy, to avoid the epiphyseal lines. Before fixing the limb on a splint, the operator must be certain that there is no pressure on the popliteal vessels.

If the ankle be ankylosed in a bad position, the astragalus must be excised.

In bony ankylosis of the elbow, I believe arthroplasty is superior to excision.

Robert Milne.

ANKYLOSTOMIASIS.—(See *ANÆMIA, TROPICAL*.)

ANOREXIA NERVOSA should be treated by isolation and forcible feeding, with or without the stomach tube—which is not often necessary, as the patient will generally swallow if fed with a spoon, and when isolated from anxious friends soon eats normally. These cases do well under Weir-Mitchell treatment, but may relapse when they return to their homes. (See also *HYSTERIA*.)

Robert Saundby.

ANOSMIA.—The treatment of anosmia depends entirely upon the cause. It may be (1) *Obstructive*, that is, due to any form of nasal obstruction which prevents the access of the olfactory particles to the olfactory area; (2) *Essential*, that is, an affection of the olfactory mucous membrane or nerve-endings; and (3) *Central*, that is, disease or injury of the brain or of the olfactory nerve or nerve centre. In the first form the treatment consists in the removal of the cause. If this can be effected, recovery may take place, although the sense of smell has been in complete abeyance for years. The most common cause of this form of anosmia is nasal polypus or œdema of the middle turbinate, such as may occur in sinus suppuration, or, temporarily, in a simple cold. The

chief causes of essential anosmia are poisons, such as cocaine, morphia, and tobacco, and the toxins of influenza and syphilis. The treatment consists in the elimination of the cause. In syphilitic cases, iodide of potassium must be given; in influenza, the most hopeful treatment is the internal administration of large doses of strychnine and phosphorus; arsenic also may be tried. Good feeding and change of air are beneficial. In central anosmia due to lesions of the brain, little can be done, but if the loss of smell be due to neurasthenia or hysteria, appropriate general treatment will often effect a cure.

H. Lambert Lack.

ANTHRAX.—In the external form the pustule must be excised, all affected tissue being removed as completely as possible. The resulting raw surface should be swabbed with carbolic acid (1–10). A few minims of a 1–20 solution of carbolic acid, in equal parts of water and ether, should be injected in six or seven places round and beneath the wound. A compress of the same solution should be applied, and over it an ice-bag (J. H. Bell). Instead of carbolic acid, potassa fusa, or chloride-of-zinc paste, may be applied to the wound. Gräff advises, instead of excision, the cauterization of the pustule by rubbing it firmly and thoroughly with solid caustic potash. Ipecacuanha powder, externally (after excision) and internally, has been strongly recommended by Dr. Muskett and the late Mr. Davies-Colley. In addition to local treatment, 20 to 60 c.c. of Sclavo's serum should be injected hypodermically, and repeated if necessary. This serum is stated to be both antimicrobial and antitoxic. Such favourable reports have been published concerning it, that it should certainly be given a trial in all forms of the disease. If the serum is not readily obtainable, pyocyanase (a vaccine prepared from the *B. pyocyanus*) may be employed. Good results have also been claimed for salvarsan (0·3 gram intravenously). (See also SPECIFIC THERAPY, and FEVERS, ACUTE INFECTIOUS.)

E. W. Goodall.

ANTRUM, SUPPURATION IN.—(See NOSE, ACCESSORY SINUSES OF.)

ANURIA.—(See URINE, SUPPRESSION OF.)

ANUS, SURGICAL DISEASES OF.

Anal Abscess. (See ABSCESS.)

Epithelioma of the Anus (see also RECTUM, CANCER OF).—Wide and extensive removal of the growth at the earliest opportunity is the only treatment. The sphincters must be unhesitatingly sacrificed, together with a wide area of skin round the growth, and it is best to perform a preliminary colotomy, so as to give the patient control over the evacuations and prevent contamination of the large wound which must result from removal of the growth. As the whole anal region and sphincter muscles have to be removed, the patient is better off with a colotomy than he would be if any attempt were made to bring the bowel down. The question of removing the glands in both groins at the same time must also be considered, as these glands not infrequently are involved early. Radium and α rays should never be used as a substitute for operation when the latter is possible; but as a means of preventing recurrence, radium treatment is of value, and in inoperable cases it is sometimes of great service.

Anal Papillomata (Warts).—The commonest forms of anal warts are the condylomata which occur round the anus as a manifestation of secondary syphilis. These as a rule require no special treatment beyond that necessary for the constitutional malady. There is, however, a rare form of anal papilloma which is not syphilitic; the tumours hang in bunches like grapes, and are often very numerous. There is in such cases sometimes an antecedent history of secondary

syphilis, but the condition is not affected by antisyphilitic treatment; these warts often result from chronic rectal discharge; they should be cut off with scissors under proper antiseptic conditions, care being taken to see that undue contraction of the anal orifice will not result from the healing of the wounds. They will often disappear without being cut off if kept dusted with calomel, or if rubbed over with copper sulphate.

Fissure of Anus.—By this we understand an ulcer just within the grasp of the external sphincter, which calls for treatment on account of the extreme pain which it causes, and because it may result in a fistula. The only certain method of curing a fissure is to incise its base in such a manner as to ensure that there is a free drain for the discharges on to the surface of the skin. With this object the incision must be brought well out on to the skin. Palliative treatment with ointments, etc., is only successful in very slight cases; the time required for healing is often considerable, and the results are often unsatisfactory. Incision, properly carried out, is followed by immediate and complete cure.

OPERATION.—The external parts are cleansed as well as possible, and the patient is anæsthetized. A straight cut is then made with a knife from the uppermost limits of the fissure straight through its base and well out on to the skin. The incision must be deep enough to divide all the base of the fissure and the outer fibres of the external sphincter muscle. The edges of the incision should be trimmed off so as to leave a flat wound rather than a slit. Any bleeding that occurs is easily stopped by pressure. A small piece of wool is placed in the cut and a bandage applied. If the fissure be complicated, as it often is, by a small polypus or external pile, this is cut off with scissors at the same time. The wound should be dressed daily and the patient kept lying down till the wound is quite healed. There is no necessity to divide the sphincter muscle; all that is required is the provision of adequate drainage.

If a general anæsthetic is contra-indicated, the incision can easily be made under local anæsthesia. For this purpose some of the following solution should be injected with a fine hypodermic needle beneath the base of the fissure before making the incision:—

R β -Eucaïne Hydrochl. (4%) 9 parts | Sol. Adrenalin (1-1000) 1 part

A cure can sometimes be effected by simply stretching the sphincter, but this must be done under a general anæsthetic, and it is unreliable; or in very slight cases the patient may be kept in bed and the bowels kept acting loosely with an aperient, and in addition some such ointment as the following may be squeezed into the anus:—

R Bismuthi Subnitratís gr cxx | Vaselini 3j
Cocainæ Hydrochloridi gr viij

This should be in a collapsible tube with a bone nozzle, or used with an ointment introducer. Operation, however, is the best treatment, and the quickest in the end. Fissures should never be neglected, as they often cause fistulæ.

Fistula in Ano.—There is no treatment other than by an operation. When a fistula has been detected it should be operated upon as soon as possible; a much more severe operation may have to be performed if it is neglected. Fistulæ are often divided into blind internal, blind external, and complete, but the treatment is the same in each case.

OPERATION.—This consists in freely laying open the fistula by a grooved director and knife, and then laying open all the side tracks, if there are any. If a single pocket or tract is missed, the operation is almost certain to be a failure, and it is here that the difficulty of successfully operating for fistula arises. The sphincter should never be divided in more than one place, and care should be taken not to cut the muscle fibres on the slant. It used to be supposed

that division of the sphincter muscle was necessary to obtain healing of a fistula. This is, however, not the case. Most fistulæ do not pass deep to the external sphincter muscle, and it is not necessary to divide this muscle; free and adequate drainage of the fistulous track is alone necessary, and the sphincter should never be divided unless drainage of the fistulous track is not otherwise possible. Small straight fistulæ should be cut out. Large and tortuous fistulæ must be laid open freely and all granulation tissue scraped away. Not only should the fistulous tracks be laid open, but the edges should be cut away, bearing in mind that the object is to leave a wound without pockets, which will have the freest possible drainage on to the skin surface. The wound should not be plugged, but just lightly packed with wool or ribbon gauze. Subsequent treatment should consist of daily baths, in which the packing should be soaked out, followed by irrigation of the wound with sterilized water or 1-60 carbolic and *very light* packing with strips of wool. The patient should not be allowed to get up until the wound has soundly healed. It must be kept clean, as if sloughing occurs serious contraction is likely to result.

Contrary to what is often supposed to be the case, the operation for fistula requires special skill and considerable experience if a cure is to be obtained. This is well known to those surgeons who make a speciality of rectal surgery, for nearly half the patients presenting themselves for treatment have previously been operated upon, many of them several times.

(See also COLOTOMY, and PRURITUS ANI.)

J. P. Lockhart Mummery.

AORTIC VALVULAR DISEASE.—(See HEART, VALVULAR DISEASES OF.)

AORTITIS.—(See ARTERIOSCLEROSIS.)

APHASIA (in Hemiplegia).—Right-sided hemiplegia is nearly always associated with some defect of speech, except in left-handed people. In some cases the defect is transitory, in others permanent. If transitory, it is either because the speech centres and their connections on the left side of the brain are temporarily damaged, but not destroyed, or because those on the right side take on the function of those on the left. If permanent, it is probable that not only the speech centres on the left side and their inter-connections or commissures are destroyed, but the path through the corpus callosum between them and the right-sided centres is broken.

It is impossible in a given case to say whether or not the callosal fibres are interrupted, and therefore each case should have the benefit of the doubt, and treatment will aim entirely at *re-education* of the right-sided speech centres when those on the left side have been injured.

The varieties of speech defects in hemiplegia are numerous and complicated. Only the simple and uncombined forms can be considered here, with reference to treatment.

Aphasia may be (a) *Motor*, (b) *Sensory*.

a. In purely **Motor Aphasia** the patient understands spoken and written or printed words and sentences, but mispronounces and cannot articulate, or he utters "dead propositions" or set phrases such as "dear, dear!" whenever he speaks. He is conscious of this defect. He may be able to write spontaneously or at dictation, and to copy—after practice—with his left hand. The treatment consists in endeavouring to teach him to articulate on the oral system, as practised in the deaf and dumb.

b. **Sensory Aphasia** may be *Auditory* or *Visual*.

In *Auditory Aphasia* there is "word deafness." The patient cannot understand spoken words, although he hears them. He can copy, but cannot write

at dictation. He may be able to speak, but uses wrong words without knowing it, in contradistinction to the motor aphasia.

The treatment consists in endeavouring to rouse the *visual* memory of words and objects when audition of their names and sounds conveys no meaning. Thus, a spoken word should be written or shown in print, and the object or a picture of it displayed, whilst mentioning its name to the patient.

Word Blindness.—Here the patient may be able to write spontaneously or at dictation, even with eyes shut, but does not understand written or printed words, nor can he copy. He cannot read aloud (Alexia). Treatment consists in teaching him to trace written or printed letters with his finger in the air, or to use the "Braille" raised-letter system as employed for the blind.

The combination of "word blindness" and "word deafness" constitutes "mind blindness," in which the unfortunate patient recognizes neither persons, objects, nor words.

Here it is only possible to attempt to educate the sense of touch, a method which proved of signal success in the cases of Laura Bridgman and Helen Keller, who were deaf, dumb, and blind.

Verbal Amnesia is usually associated with some word deafness and motor aphasia. In its simplest form the patient cannot recall words or the names of objects. He can copy and understand written and spoken language, but cannot write spontaneously. He may be able to write a single word at dictation. He can repeat words and names of things at dictation, but immediately forgets them. He should be encouraged to repeat strings of words and names over and over again, his vocabulary being daily enlarged.

Agraphia.—In all cases of right-sided hemiplegia the patient should be encouraged to write with his left hand, and indeed to use his left hand as much as possible, for working and other purposes, in order to stimulate the right side of the brain. When motor aphasia is present, however, attempts to write are often impossible until the patient has recovered some power of articulate speech.

When word and letter blindness are not present, the curious errors, such as repetition of syllables and substitution of consonants, which render writing unintelligible, may be overcome by practice of copying.

In all cases of aphasia the principle of treatment is to observe first the main defect, and then to devise appropriate exercises to remedy it. Such exercises should be of the simplest nature at first, and each should be mastered before more complex ones are attempted.

Exercises should never be practised long enough to cause fatigue, and should be repeated frequently, for short periods, during the day. *Leonard G. Guthrie.*

APOPLEXY.—(From Cerebral Hæmorrhage, or Occlusion of Cerebral Vessels.) (See also HEMIPLEGIA.)—Apoplexy implies loss of consciousness, of sensation, and of voluntary movement, occurring, more or less suddenly, in consequence of rupture or occlusion of cerebral vessels. Both cerebral hæmorrhage and occlusion of vessels may take place without loss of consciousness, but in this paper only cases in which unconsciousness attends or supervenes on either condition will be considered as apoplexy.

Deep and instantaneous coma is rarely the result of an intracerebral vascular lesion. When it occurs, the lesion is usually so extensive as to render treatment hopeless.

Most cases of apoplexy may be divided into two stages, which it is important to recognize, as each requires treatment appropriate to its cause:—

1. *The Initial Shock.*—Collapse or syncope, with loss of consciousness, often preceded by sudden vertigo, pain in head, and vomiting. To this stage the

term "cerebral surprise" has been applied. It is usually followed by a rally or return to consciousness, succeeded more or less gradually by :—

2. *The stage of Apoplectic Coma.*

DIAGNOSIS is always a matter of probability rather than of certainty. Guidance is afforded by knowledge of the various causes, by the patient's age, and the condition of his heart, vessels, circulation, and kidneys, and by his history. Hæmorrhage may be suspected in the middle-aged and elderly; occlusion of vessels in the old and young. Hard arteries are not proof of hæmorrhage, but high arterial tension is in favour of it. Chronic Bright's disease is the most frequent cause of hæmorrhage. In young adults, not subjects of chronic interstitial nephritis, thrombosis or embolism is more probably the cause than hæmorrhage. Embolism is most likely in cases of mitral stenosis, or in cases calculated to promote intracardiac thrombosis. In young adults, too, in whom no other cause can be detected, thrombosis due to syphilis may be divined.

Some help is afforded by the mode of onset. "Cerebral surprise," or initial shock, is most commonly the result of sudden hæmorrhage, or occlusion of a large vessel by embolism.

In thrombosis, premonitory symptoms, such as headache, mental confusion, giddiness, weakness, or paræsthesia of limbs, are fairly common. It should be remembered that hæmorrhage not infrequently takes place into areas previously softened by the effects of thrombosis.

Post-epileptic coma may be indistinguishable from apoplexy except by eliciting a history of former epileptic fits. Narcotic coma can be distinguished from apoplexy only by circumstantial evidence. Hæmorrhage into the pons varolii strongly simulates opium poisoning. In the former the temperature is usually high; in the latter it is low. Diabetic and uræmic coma must be thought of, but are hardly likely to be confounded with apoplexy when the patient's history is known. Albuminuria is in favour of hæmorrhage.

Finally, cerebral hæmorrhage is not confined to stout, plethoric, short-necked, quick-tempered, gouty individuals, who indulge in gross feeding and alcohol; it may occur also in meagre, debilitated ascetics.

I.—APOPLEXY FROM CEREBRAL HÆMORRHAGE.

TREATMENT.—The treatment of intracerebral hæmorrhage naturally falls under two headings: (1) To arrest bleeding from the ruptured vessel; (2) To relieve pressure-symptoms produced by the extravasation. In both, treatment must be based on physiological and pathological data, and also on the symptoms present.

1. TO ARREST HÆMORRHAGE.

Bleeding from a ruptured intracerebral artery cannot be directly controlled. The vessel cannot be compressed or tied. Probably, arrest of hæmorrhage would never take place before the patient died were it not for pressure of the extravasated blood upon the ruptured vessel, and sealing of the aperture by spread of coagulation. It is only possible to favour coagulation by lowering the flow of blood through the perforated artery.

Effects of Shock or Syncope.—The initial shock or collapse caused by the giving way of an intracerebral vessel will tend to stay the hæmorrhage by reducing arterial blood-supply. Hence strenuous efforts to rouse the patient and to restore consciousness under this condition are inadvisable. The hæmorrhage may recur with the return of consciousness.

Initial shock from hæmorrhage is unlikely to be fatal unless the rent in the ruptured vessel be large. Masterly inactivity is the best policy. Injections of strychnia, digitalis, ether, and brandy, should be avoided.

Absolute rest in recumbent position, with head and shoulders slightly raised, should be secured. The room should be cleared, if crowded, and kept airy; the patient's collar should be taken off. Life may usually be sustained by warmth; hot flannels may be applied to the præcordia, hot bricks or bottles to the feet and between the thighs.

Brandy, almost invariably, will have been poured down the patient's throat in more than sufficient quantity before the doctor arrives. When otherwise, a few drops may be placed on the tongue or used to chafe the lips. To avoid the imputation of doing nothing, anxious relatives and bystanders may be despatched on various quests for hot water, bricks, blankets, bottles, pillows, rugs, and sal-volatile.

Rest and warmth are the best means of retaining life, without endangering it by starting hæmorrhage afresh.

Whenever possible, the patient should be kept for at least twelve hours in the place where the seizure has occurred. When removal home or to a hospital is unavoidable, it should be effected in an ambulance, not in a four-wheeled cab. When a bulky man is seized by apoplexy in a dining-room, it is safer to improvise a couch for him there than to convey him to a bedroom upstairs. Unfortunately, as soon as he regains consciousness, he usually at once insists on walking upstairs or going home. Recurrent hæmorrhage follows in consequence. Many lives have been thus sacrificed.

Syncope probably checks hæmorrhage and allows time for coagulation to occur. Unless it be so profound as to endanger life, it should not be energetically treated. With reaction from syncope, hæmorrhage may be renewed, with symptoms of so-called ingravescent apoplexy. The patient becomes increasingly drowsy until comatose. Localizing signs, such as hemiplegia, make their appearance.

The methods designed to stay recurrent hæmorrhage are :—

i. *Arterial Depletion*.—The indications for arteriotomy of the temporal artery were long considered to be a forcible, rapid, or slowly heaving heart, with a full, bounding, incompressible pulse.

Undoubtedly a powerfully acting heart, together with a condition of general high arterial tension all over the body, will increase the force and rapidity of the blood-flow through the ruptured artery in the brain. Hence it seemed the obvious course to let out blood from over-filled arteries. Temporary benefit from cutting the temporal artery was often remarkable. The patient quickly recovered consciousness, even whilst the blood was flowing, but speedily lost it again, because he fainted. If he died, some said he was bled too much, and others, not enough. The former conjecture was probably correct.

On pathological grounds it is difficult to see how arteriotomy could be beneficial. The general high tension which prevails in most cases of cerebral hæmorrhage is due not to absolute but to relative plethora, consequent on general vasomotor constriction. Abstraction of a large quantity of arterial blood under these conditions might certainly relieve cardiac labour, but only momentarily, for, given continuance of vasomotor constriction, high tension must soon recur, and in a patient rendered weaker than before by loss of arterial blood. Arterial blood is life. It cannot be profitable to lose it. In the case of venous blood it may be otherwise. If, as stated, high arterial tension and blood-pressure depend upon narrowing of the calibre of arteries and arterioles in general, the most reasonable course would be to *increase the calibre of the blood-vessels* rather than to *diminish their contents*. The result would be to flood the body in general with arterial blood, and so deplete the cerebral arterial supply; for the cerebral vessels have no efficient vasomotor system, and therefore when the general arterial system is contracted the cerebral arterial supply is increased.

Crude methods of "determining blood" to the surface and extremities so as to diminish the supply to the brain have always formed part of the stock treatment of cerebral hæmorrhage. Sinapisms, rubefacients, hot irons, Burgundy pitch plasters to the calves and soles of the feet, blisters to the nape of the neck and to the shaven scalp—"universo capiti"—were styled counter-irritants, but were really barbaric means of withdrawing blood from the brain to distal parts. Their net result could only irritate. Celsus summed them up as "means which often only delay death when it seems at hand, and meanwhile prove troublesome to life." Less antiquated methods which have been used are "Junod's boot," in which air is partially exhausted around the limbs and the application of constricting bandages to their proximal parts. Local measures of the kind can be of infinitesimal value only.

The use of a hot-air cradle over the lower limbs is perhaps reasonable in theory, but has the disadvantages of raising the temperature generally and quickening the pulse. If used, the temperature of the air-bath should not exceed 180° F. or thereabouts.

Nitrite of amyl and nitroglycerin produce flushing, throbbing of vessels, headache, with dilatation of vessels, fall of general arterial pressure, and *greatly diminished cerebral circulation* (Hill). Hence, when vasomotor constriction is producing high arterial blood-pressure and increased cerebral circulation, the use of nitrites would seem to answer all purposes required, without the disadvantage attending arteriotomy. The objection which may be raised against nitrites is that by their direct action on the blood they may increase asphyxia, which, after all, is the chief danger to be apprehended in cerebral hæmorrhage. Their utility in cases of generalized arteriosclerosis in decrepit elderly subjects is doubtful, but in youngish patients whose vessels are on the whole sound, though in a condition of generalized constriction, nitrites may prove valuable.

Inutility of other Drugs as Hæmostatic Agents.—Such drugs as ergot, adrenalin, digitalis, and strychnine, which raise arterial blood-pressure by causing contraction of arterioles, cannot be recommended in cerebral hæmorrhage. The main object of treatment is to keep arterial blood-pressure low. In the majority of cases the pressure is already too high. The above-named drugs can only increase it if the contractile elements of the vessels are in working order. Chloride of calcium has been suggested owing to its action in increasing the coagulability of the blood. If it could be employed for some days before the occurrence of the hæmorrhage, no doubt it might be beneficial. To use it afterwards would seem to be as reasonable as to attempt to stop a leak in a water-pipe by putting plaster-of-Paris in the cistern.

ii. *Direct Compression of the Carotid Artery.*—If one can be certain that bleeding has occurred from an intracerebral branch of the carotid, e.g., middle cerebral, and not from a branch of the postcerebral or basilar, compression of the common carotid is a logical procedure. Ligature of the vessel is an operation too formidable to need consideration.

Finally, hæmostasis may be favoured by keeping the head and shoulders slightly raised and the feet dependent. Application of an ice-bag or of Leiter's tubes to the head may perhaps be beneficial.

2. TO RELIEVE THE PRESSURE SYMPTOMS.

The Second or Pressure Stage of Cerebral Hæmorrhage.—The symptoms are coma, with stertor, us, laboured, irregular respiration, lividity or congestion of face, turgescient throbbing cervical veins, glistening conjunctivæ, pupils dilated or contracted, nystagmoid movements of eyeballs, and sometimes convulsions. Respiration gradually fails, may become of Cheyne-Stokes variety, or gasps may occur at increasing intervals, until the last breath is drawn. The pulse at first may be full and bounding, quick or slow. Later, arterial blood-pressure falls as signs of pulmonary obstruction appear, and the

air-passages become choked with bronchial secretion. The pulse then becomes small, weak, and irregular, the right side of the heart dilates, becomes engorged, and blocks the entry into it of venous blood. As a rule the heart continues to beat after respiration has ceased. Death is due to asphyxia.

The symptoms are those of acute cerebral anæmia. They are produced by compression of cerebral vessels by the extravasated blood. Anæmia, thus caused, affects the bulbar respiratory centres, and so gives rise to asphyxia and gradual respiratory failure.

Asphyxia in apoplectic coma is also partly due to mechanical obstruction to air-entry into the lungs. This is indicated by the familiar stertor, and is caused by paralysis of tongue, palate, and cheeks, and by weakness of respiratory muscles and accumulation of mucus in the bronchi. Such mechanical asphyxia impedes the return of cerebral venous blood to the heart, and thus causes cerebral venous congestion, which aggravates intracerebral pressure already occasioned by the hæmorrhage.

Venous congestion and anæmia produce similar effects; both starve the respiratory centre of oxygen.

Treatment should aim at (i) Relief of direct pressure on the brain by the existing clot; and (ii) Prevention or counteraction of secondary pressure (venous congestion) occasioned by mechanical asphyxia.

i. *Methods of treating Cerebral Compression caused by Hæmorrhage.*—In traumatic cases, when the bleeding is from a meningeal vessel, and upon the surface of the brain, the obvious course is to trephine, close the bleeding vessel, and turn out the clot. The method in such cases has been strikingly successful, but is inapplicable in most cases of spontaneous intracerebral hæmorrhage. In a few selected cases, however, "decompression" operations—with or without attempts to evacuate extravasated blood—as practised by Harvey Cushing, Osler, and others, may be justifiable. Craniectomy alone, to be of service, must be extensive, for Hill has shown that removal of a small circle of bone gives no relief, as the brain presses up against the trephine hole and closes it like a valve.

A student, aged twenty-five, under care of Wilfred Harris, had suffered for a fortnight from severe symptoms of intracranial pressure. Professor Pepper trephined and let out one and a half ounces of blood from the interior of the brain. The patient made a complete recovery. Russell and Sargent trephined a woman aged fifty-four, who had been comatose and hemiplegic for ten days, explored the brain, and evacuated three drachms of blood from a cyst situated two and a half inches beneath the cortex. This patient also survived, but was still aphasic and hemiplegic nine months later. Russell and Sargent recommend operation when there are "strictly unilateral symptoms indicative of a localized hæmorrhage in the white matter, not flooding the ventricles, with deep coma and high blood-pressure."

It must be admitted, however, that in similar conditions recovery may be spontaneous, even after coma of six weeks' duration. Operations of any kind are clearly contra-indicated in elderly patients with advanced cardiovascular changes and renal disease. The temporary improvement and fall of blood-pressure noted in operation cases which ended fatally, may be attributable to loss of blood alone. Sub-cortical hæmorrhages causing pressure symptoms in young subjects are most suitable for operation. Even in these, success will depend chiefly on the degree of fluidity of the extravasated blood. A firm coagulum cannot be extracted without additional damage to the brain itself, and at the risk of exciting hæmorrhage afresh.

The difficulty in diagnosing hæmorrhage from occlusion of cerebral vessels has to be borne in mind. An operation conducted under a mistaken diagnosis would be useless and probably fatal. It may be concluded that in the great majority of cases no surgical treatment can obviate the results of direct compression of cerebral vessels by a clot in the interior of the brain. We can only try to prevent increase of the pressure which already exists.

Lumbar puncture has been recommended, but it is difficult to see how it can relieve intracranial tension due to hæmorrhage or œdema. Also the sudden withdrawal of cerebrospinal fluid may lead to the medulla being forced down into the foramen magnum, with immediate disastrous results.

ii. *Asphyxia*, due to mechanical obstruction of respiration, may be combated by drawing forward the tongue and chin, and placing the patient on his side, so that secretion may trickle out of the mouth instead of passing down the trachea. He should lie on the paralyzed rather than on the non-paralyzed side, in order to allow the latter some scope for action. When the bronchi are becoming choked with mucus, injection of atropine may check the secretion. Atropine may also be useful in stimulating the respiratory centre and in lowering arterial tension.

Venous Depletion, indirect and direct.—Purgation by calomel or croton oil answers the purpose of indirect depletion, and may in clear cases of cerebral hæmorrhage be recommended. *Venesection* fell into disrepute in apoplexy because it was carried to excess, and was used indiscriminately for all cases of unconsciousness, whether due to hæmorrhage, occlusion of cerebral vessels, or simple syncope. The indications for venesection are, however, fairly clear, and if correctly observed it is difficult to believe that abstraction of a few ounces of venous blood can be otherwise than beneficial in cases of cerebral hæmorrhage in the second stage. The condition which venesection may relieve is venous congestion of the brain, intensified by obstruction to exit of the blood from the right heart, such obstruction being the result of asphyxia.

When the right heart becomes engorged and unable to empty itself, backward pressure spreads to the jugular, and thence to the cerebral veins; a condition which aggravates pressure already produced by the intracerebral clot. The condition can be rationally treated only by temporarily aiding the right heart and removing the intravenous cerebral pressure by tapping a vein.

The condition which warrants venesection is manifested by a full, tense pulse, a labouring heart, with failure and acute distention of the right auricle and ventricle, and engorgement of the cervical veins. Venesection is contra-indicated by a weak, small, fluttering pulse with failure of a chronically (not acutely) dilated heart in debilitated, aged subjects.

When coma is profound and lasting, and the hæmorrhage extensive, venesection is unlikely to afford even temporary benefit; but when venous engorgement and distention of heart and veins have been largely brought about by mechanical obstruction of respiration, venesection, together with means to secure free entry of air into the lungs, may tide the patient over the immediate danger of death from asphyxia. Venesection may in fact relieve an acutely distended heart in those circumstances, as it undoubtedly does in cases of distention due to purely intrathoracic causes of obstruction.

Methods of Venesection.—Although it would seem most rational to draw blood from the external jugular vein, with a view to relieving at once both heart and brain, it is safer, easier, and perhaps as efficacious, to open a vein at the bend of the elbow, in the usual manner.

The opening in the vein should be free, and not more than 8 or 10 oz. of blood should be withdrawn—as speedily as possible. The operation should never be repeated. When it is found impossible to overcome the prejudice of the patient's friends against bleeding, the application of two or three leeches to each mastoid process may be recommended; or dry cups may be employed extensively over the chest. Dry cupping is painless, and causes but little disturbance to the patient.

Diuretics are probably of little value, but distention of the bladder should be looked for, and relieved by catheterization, even when there is incontinence of urine.

Finally, to avoid entry of food into the larynx, an unconscious patient should be fed by nasal tube. The danger of bedsores and burns by hot bottles should be anticipated.

II.—APOPLEXY FROM OCCLUSION OF CEREBRAL VESSELS.

TREATMENT.—In hæmorrhage, as we have seen, the main desiderata are a quietly working heart and low arterial tension, in order to favour stagnation and hasten coagulation at the site of the injury.

In occlusion by thrombosis of a cerebral artery, one desires to stimulate the heart, raise arterial tension, and accelerate the circulation, in order to lessen the tendency to further coagulation.

Initial Shock or Syncope produced by Occlusion of Cerebral Vessels.—Although probably beneficial in hæmorrhage, syncope must be the reverse in cases of vascular thrombosis, and it is therefore important to revive the patient as speedily as may be.

Warmth is essential. Bags of hot water should be applied to the præcordia, heat being the best of cardiac stimulants. The patient should be recumbent, the head and shoulders low, but not too low, lest return of venous blood from the brain be impeded. The foot of the bed should be a little elevated. As soon as consciousness returns, the head and shoulders may be raised slightly and the end of the bed lowered.

Stimulants must be given, but not too freely. Physiological considerations must be subservient to pathological conditions present. For in thrombosis due to local atheroma, excessive stimulation may rupture the weakened vessel, and cause hæmorrhage into an area of brain already softened, and thus make matters worse. Such hæmorrhage is by no means uncommon. Again, in cases of embolism from detachment of fibrin from a diseased cardiac valve, vigorous stimulation may dislodge another embolus.

A single dose of ether and ammonia, or a tablespoonful of brandy, may be given at once; smelling salts or burnt feathers may be held under the nostrils. Such measures will be sufficient to cause a rally, without undue vascular excitement.

Purgatives.—The common custom of giving, indiscriminately and at once, croton oil or a large dose of calomel to all patients who are found unconscious and hemiplegic, cannot be too strongly deprecated. Infinite harm may be done by drastic purgation in cases of thrombosis. The patient is weakened thereby, and his blood rendered more coagulable than before. It is a safe rule to avoid drastic purgatives in all cases of apoplexy in early stages, except, perhaps, when the diagnosis of hæmorrhage in robust, plethoric, heavy-drinking and large-eating individuals, is clear.

When consciousness returns in cases of vascular occlusion, a dose of castor oil, followed if necessary by a simple enema, is quite sufficient to secure evacuation of the bowels.

To Prevent the Spread of Coagulation.—Arterial tension may be raised, cardiac force increased, and circulation quickened, by cardiovascular stimulants. The indications for their use must depend upon the actual condition of the cardiovascular system. For instance, such drugs as strychnine, digitalis, and ergot may, by causing extreme vascular constriction, seriously embarrass a weakened and dilated heart. Except in cases in which extensive degeneration of the walls of arteries and arterioles precludes the possibility of their reacting physiologically to drugs, cardiac stimulants should be combined with vascular dilators, such as nitroglycerin.

Nitrite of amyl and nitroglycerin alone are contra-indicated in thrombosis of cerebral arteries, owing to their action in depleting cerebral vessels by

lowering systemic arterial pressure. But this effect may be counteracted by giving digitalis or, better still, strychnine, simultaneously. With this object, nitroglycerin in one-drop doses of the 1 per cent solution may be given with 2 or 3 min. of liq. strychninæ, 1 per cent. On the other hand, it must be remembered that neither vasomotor dilators nor constrictors can have much action on vessels whose walls are extensively atheromatous and rigid. After death in such cases one may find the brain substance softened to fluidity, and the vessels suspended in it like branches of dried seaweed. Treatment in these conditions is obviously futile.

Powerful cardiac stimulants can only, as said before, tend to burst atheromatous and thrombosed vessels, by increasing cardiac force and rapidity. Strychnine, strophanthus, digitalis, and perhaps ergot, may be given when thrombosis seems to be the result of general enfeeblement, cardiac weakness without disease, and morbid blood-conditions.

Thrombosis due to Syphilitic Endo- and Peri-arteritis.—No cases seem to be more promising for the success of treatment, and yet are more disappointing, than these. The hemiplegia which results is often permanent, and antisiphilitic treatment is useless. This is doubtless because if blood-supply is cut off from an area of the brain for any length of time, the brain tissue dies. However, in a certain proportion of cases the circulation is not entirely cut off—the nutrition of the brain is merely impaired, and may be restored. Therefore, in all recent cases, when the diagnosis is certain, the patient should be subjected to mercurial treatment. Inunction with mercurial ointment until slight salivation occurs is the best course. The innumerable preparations of mercury for subcutaneous or intramuscular injection are yet on their trial. Many of them seem not to be absorbed after injection, and practically all are painful. The iodides may be given in small doses (7 to 8 gr.) three times daily, but large doses should be avoided, on account of their tendency to promote coagulation.

Salvarsan, if shown by experience to fulfil expectations, would seem to be specially useful in cases of early hemiplegia due to syphilitic cerebral arteritis. The usual dose at present is from 0·4 to 0·5 gram (6 to 7½ gr.), given intravenously in half a pint of a neutral solution or in distilled water (see also *SYPHILIS*).

Treatment of Coma following Vascular Occlusion.—Deep coma is less common in cases of occlusion of cerebral vessels than in those of hæmorrhage; but when a large vessel is plugged, it may occur with resolution of limbs and interference with respiration as profound as in hæmorrhage. The symptoms are in fact the same as those of pressure by intracranial hæmorrhage, and considering that diminution of cranial contents rather than increase must be the result of blockage of a large vessel, it is difficult to explain their occurrence.

The investigations of Mott, Horsley, and others, however, have shown that pressure symptoms are due to anæmia of the bulb, a condition produced as much by hæmorrhage as by cutting off the cerebral arterial blood-supply, or by intracerebral venous congestion. Deep coma following occlusion of cerebral arteries is therefore due both to anæmia and to venous congestion, which must necessarily be the consequence of arterial blockage.

When, therefore, signs of respiratory embarrassment with venous engorgement and cardiac dilatation are present, the treatment does not differ from that of the same condition occurring in consequence of cerebral hæmorrhage. The danger of *mechanical asphyxia* from obstruction of entry of air into the lungs should be averted by attending to the patient's position, as in cases of hæmorrhage. When suffocation from accumulation of bronchial secretion threatens, atropine, $\frac{1}{100}$ gr., with strychnine, may be injected hypodermically, with a view to checking the secretion of mucus and stimulating respiration.

Calomel may now be given in order to relieve abdominal venous plethora. Pulmonary congestion should be treated, and the right heart relieved by dry cupping. Cerebral venous congestion may be lessened by leeching the mastoid processes. Direct abstraction of blood in these cases is regarded as inadmissible; yet venous congestion, unless relieved, will in all probability prove fatal. Venous blood is useless to the brain for the purpose of nutrition. One is therefore justified in these circumstances in attempting to relieve immediate necessities by withdrawing a few ounces of venous blood.

After-treatment of Thrombosis.—The distressing headache, due to febrile reaction, which follows thrombosis, may be alleviated by leeching the mastoid processes. No more than two leeches should be applied. Phenazone with citrated caffeine may also be administered, for relief of headache and pyrexia, and an ice-cap may be affixed to the head. Diuretics, such as spirit of nitrous ether in $\frac{1}{2}$ -dr. doses, are also useful.

Convulsions or delirium are not uncommon during the reactionary stage, and if they do not yield to the measures mentioned above, bromides in moderate doses ($\frac{1}{2}$ dr.) may be given, with digitalis.

The majority of subjects of thrombosis are debilitated and worn out. They require nutritious and easily assimilated food, but care should be taken not to overload digestive powers. Bland fluids, such as barley-water, may be freely supplied, in order to lessen viscosity of the blood. Alcohol may be needed when the heart and pulse are weak and fluttering, but should be withheld, if possible, during the reactionary or febrile stage.

The greatest care should be exercised in prevention of bedsores. The bowels should be regulated without active purgation, and retention or incontinence of urine appropriately treated. Tranquillity of mind and body is essential, for any cardiac disturbance may be followed by reactionary failure and extension of thrombosis.

Treatment of Embolism.—Treatment can neither dislodge nor dissolve an embolus. One can only hope to prevent the passage of other emboli into the cerebral circulation, and to lessen the thrombosis which succeeds embolism and makes the blockage more complete.

Complete rest is demanded in all cases. When a particle of fibrin has been detached from a diseased cardiac valve it is necessary to strengthen and steady the action of the heart; for irregularity and feebleness of the heart tend to increase the deposition of fibrin upon the valves, and excited cardiac action causes fibrin to be washed off into the circulation. Belladonna, strophanthus, and digitalis are the best remedies.

Embolism is most likely to occur in young subjects of heart disease, whose arterial walls are sound, and so the precautions which must be observed in cases of hæmorrhage and widespread atheroma need not, with regard to the drugs mentioned, be considered, as a rule, in cases of embolism.

In cases arising from detachment of a clot which has formed in the auricle—a condition associated with exhausting illness such as enteric fever or diphtheria, or with loss of blood after parturition or profound anæmia—cardiac tonics are needed, and attempts should be made to lessen coagulability of the blood. With the latter object, transfusion of saline solution, rectal, subcutaneous, or intravenous, may be practised. When embolism is associated with septic inflammation in the pelvis or elsewhere, treatment of course must chiefly deal with such local conditions. The possibility of the formation of a cerebral abscess in such cases should not be overlooked.

* * * * *

In conclusion, it must be added, that in most cases of apoplexy we have to deal with damaged hearts, kidneys, vessels, and morbid conditions of the blood.

The treatment of such pathological states on purely physiological grounds is fallacious. As Hippocrates said, "Grave apoplexy is impossible, and mild is not easy, to cure." Recovery in a large proportion of mild cases is spontaneous, and more or less complete. Active treatment is therefore unnecessary and may be dangerous. In grave cases, treatment may be useless; yet that is no reason why it should be withheld when the symptoms and physical signs suggest rational measures for their relief.

Leonard G. Guthrie.

APPENDICITIS.

ACUTE APPENDICITIS.

These cases fall into three groups: (1) *Those in which the disease is recognized at its onset*; (2) *Those seen by the surgeon, or in which the diagnosis is made, when the disease has spread outside the appendix*; (3) *Those with a localized abscess.*

The ideal treatment is to remove the appendix before infection of the general peritoneal cavity has occurred, within the first few hours of onset. The 'mildness' of the attack should never be allowed to postpone operative interference. Early operation should be strongly urged in every case. It is impossible to foretell the course of events; and in skilled hands the patient is convalescent, without his appendix, with infinitely less danger and in less time than if the attack had been medically treated.

1. Cases seen within the first twenty-four to thirty-six hours.—Operation should be carried out at once. Aperients or enemata should not be given; no pre-operative treatment is necessary. If the patient has to be removed from home for operation, it is wise to give an adequate injection of morphia, and transport sitting up.

As in all acute abdominal cases, 'open ether' preceded by a hypodermic injection of $\frac{1}{200}$ to $\frac{1}{100}$ gr. of atropine is at present the best anæsthetic. Chloroform should never be employed. The incision should be the muscle-splitting one in the right iliac fossa, unless symptoms point to the appendix occupying a position in the pelvis, or to its being associated with a high cæcum; in both of these cases the onset is often subacute. I believe this incision to be superior to the Battle incision, which cannot be sufficiently enlarged without endangering the twelfth dorsal nerve; this predisposes to the formation of inguinal hernia. The opening into the abdominal cavity should be of sufficient size to allow the appendix to be removed by sight. At this stage it is often tensely distended, and any rough manipulation or attempt to get it out through too small an opening may result in rupture and infection of the peritoneal cavity or abdominal wound. When the appendix is in the pelvis, the incision should be made over the inner third of the right rectus muscle, and the muscle reflected outwards. No drainage is necessary unless perforation has occurred or there is uncontrolled oozing from adhesions. (Free fluid, clear or turbid, is often present in considerable amount in this stage; this does not necessitate drainage.) If drainage is indicated, a tube of sufficient size should be inserted, and can in the latter case be removed in twenty-four hours, as it also can in many of the former.

The after-treatment does not differ from that of interval cases. The patient is propped up in bed, water is given as soon and as often as wished, and soft food as soon as inclination returns.

Complications, so common after operation in delayed cases, are rare. The death-rate is less than 2 per cent. On examining the London Hospital statistics, Lett found that of 162 consecutive patients operated upon within the first twenty-four hours in the year 1912 and part of 1913, only 2 died—a mortality of 1·2 per cent. The arguments in favour of operation within the first twenty-four hours are unanswerable. The death-rate is less than 2 per cent; the diseased organ is removed at a stage in which drainage can usually be dispensed

with and a ventral hernia avoided; convalescence is rapid; and a source of danger, not only to life, but to the health of other organs, is removed.

2. When the disease has spread outside the Appendix.—When the patient is first seen forty-eight hours or more after the onset of the disease, there is still a difference of opinion with regard to the advisability of immediate operation. The 'mild' attack is subsiding; in the more severe, the disease is no longer limited to the appendix but has spread to the general peritoneal cavity. These latter are the cases seen about the third day, the group in whom there is still the largest mortality. I am not in favour of the rule of operating "at sight" in any but the cases within the first twenty-four to thirty-six hours and in children, in whom operation should be carried out immediately on diagnosis.

The patient should be put in Fowler's position, nothing given by the mouth, continuous salines by the rectum, with gastric lavage if necessary. If at the end of twelve hours improvement is not taking place, operation should be resorted to. In many cases, however, the symptoms subside. After the temperature has been normal for about ten days the appendix should be removed. In this way convalescence is shortened, drainage is avoided, or, if a tube is necessary, it can be removed in a short time. Many cases which seem to be almost moribund with diffuse peritonitis recover under this treatment.

In the cases needing operation, the inflammation is diffuse; many of them are what would previously have been called cases of general peritonitis. Operation should be carried out as rapidly as possible, the appendix removed, and the abdomen drained by tube. The peritoneal cavity should not be irrigated, but any fluid present may be *very gently* swabbed up. The site of the tube or tubes must be decided at the time. It is impossible to drain the whole abdominal cavity, no matter how many tubes are employed. After a short time the tube drains only the area with which it is immediately in contact.

After operation, Fowler's position should be employed, nothing should be given by mouth, except water if thirst is great, and continuous rectal salines employed until vomiting has ceased and the pulse and temperature show signs that the condition is improving. Feeding should be started cautiously, and a beginning made with a bland liquid diet such as Allenbury or Benger's food, and the bowels left until the general condition is satisfactory. Abstinence from food, with continuous rectal salines, is the best means to combat distention. Should this, however, become very great, a full dose of pituitary extract may be given, followed by a turpentine enema in fifteen to thirty minutes. If this fails to relieve, the possibility of the obstruction being organic must be considered.

3. Cases with a localized Abscess.—These comprise the late cases. In many instances of pelvic abscess the early stages of the disease were subacute.

Treatment consists in opening and draining the abscess, and removing the appendix whenever possible. The advisability of doing this in an individual case depends much on the operator, one experienced in dealing with this type of case knowing where to look for the appendix. No rules can be laid down, except that to those whose operative experience is not large—when in doubt, drain only. The position of the incision, and the method by which the abdominal cavity is opened, must vary with each case, but it must be planned so as to be over the centre of the swelling, and to avoid dividing muscle fibres. When the abscess is pelvic, operation should be through an incision made over the right rectus muscle about an inch from the mid-line, its inner edge being defined and pulled out; this incision can be enlarged as much as is necessary without endangering nerves. When the abscess bulges into the rectum, it may be drained by this route as a temporary measure. In this, as in all cases in

which the appendix could not be removed at the original operation, appendicectomy should be carried out when recovery has taken place.

Removal of the appendix at the time of opening the abscess renders convalescence more rapid, ensures more thorough drainage of the abscess in that it is opened up to its whole extent, and enables the patient to return to work more rapidly and without the necessity of a second operation.

Complications.—With the more modern treatment of appendicitis, the death-rate has markedly diminished. In a paper published in 1905, I investigated the results of the treatment of the cases of acute appendicitis operated on in the London Hospital between the years 1892 and 1903. The death-rate in these years was 19·5 per cent. Lett, in a series of cases of acute appendicitis operated upon at the London Hospital in 1912 and the early part of 1913, found it to be only 4·3 per cent. The complications have diminished in an equally striking degree. The great majority arise in the second and third groups.

Residual abscess.—A secondary rise of temperature may indicate a residual abscess. A careful rectal examination should be made; if a swelling is discovered, it may usually be safely left until it can be opened from the rectum. If no pelvic swelling is present, other causes of high temperature, particularly pulmonary conditions, must be excluded, and a leucocyte count made. Sub-phrenic abscess must always be borne in mind (see SUBPHRENIC ABSCESS). An endeavour should be made to localize the fresh collection before operation.

Intestinal obstruction.—This is a somewhat rare, but very serious, complication which may occur in cases operated upon late. In many the obstruction is due to diffuse glueing together of intestinal coils in the pelvis, the result of peritonitis. In a few, the obstructing agent is a recently-formed band, or a portion of intestine has become kinked. When it is obvious that the obstruction is mechanical and not simply paralytic, operation should be undertaken, the adhesions separated or the band divided, with drainage of the intestine if this appears necessary.

Fæcal fistula.—This is rarely met with except after operation in cases of localized abscess. Spontaneous closure is the rule. Occasionally, when extensive necrosis of the cæcum has occurred, it is necessary to close it by operation.

Pylephlebitis (portal pyæmia).—While this has always been an unusual complication of appendicitis, it is becoming rarer as the removal of the appendix in the first few hours of the attack is becoming more common. In the cases in which it occurs, the attack of appendicitis is often so mild that the liver condition entirely overshadows it. The appendix should be removed if this has not already been done, and the liver explored. Any abscesses discovered should be drained. Several patients have recovered under this treatment.

Post-operative hæmatemesis or mælena.—This is a grave occurrence which sometimes occurs, and is usually due to acute ulcers or erosions of the stomach or duodenum. In a few cases the bleeding arises in a chronic ulcer from the spread of the inflammation. Operative treatment should never be undertaken.

CHRONIC APPENDICITIS.

The term 'chronic' is used to include all those cases of disease of the appendix in which the attack does not cause the patient to seek medical aid for an illness confining him to bed.

The pain in chronic appendicitis is not localized in the right iliac fossa—and if here, its principal seat is elsewhere. Less would be heard of failure to cure by removal of the appendix if we were sceptical of the appendicular origin of pain limited to the right iliac fossa. Pain and tenderness starting in and around this region rarely own this cause, and the appendix should never be removed for continuous pain here. In every case of suspected chronic appendicitis, every

method of examination should be employed in order to come, if possible, to a definite diagnosis.

There are two groups : (1) *With attacks of pain at irregular intervals* ; (2) *With dyspepsia*.

1. **With irregular attacks of Pain.**—The characteristic signs here are attacks of pain at irregular intervals, with periods of health free from indigestion. The pain is usually umbilical, epigastric, or sometimes left iliac. If seen during an attack, deep tenderness can be discovered in the right iliac fossa, or per rectum.

The appendix should be removed through a muscle-splitting incision in the right iliac fossa, unless from the physical signs or symptoms it is considered to be pelvic, when it should be removed through the incision previously described, in which the lower right rectus is pulled inwards.

2. **With Dyspepsia.**—In this group, even if a tentative diagnosis is made, it should never be acted upon alone, but the whole abdomen should be explored through an incision pulling the right rectus inwards.

James Sherren.

ARRHYTHMIA.—(see HEART, IRREGULARITY OF.)

ARTERIES AND VEINS, WOUNDS OF.—(See WOUNDS OF ARTERIES AND VEINS.)

ARTERIOSCLEROSIS* is not a clinical but a pathological name. The arterial tree, as a whole or in parts, may undergo injury or deterioration in the course of more than one series of morbid events ; moreover, however closely in the advanced stages the diseased vessels may resemble each other in their superficial, or even in their histological aspects, it is probable that the intimate process of damage or decay is not uniform. If, towards the end of their life, they all abut upon a common form of decay, there may be nevertheless, and probably there are, several processes of initiation, each with its own primary pathological features.

In this article we have no direct concern with the histology of the subject ; yet, as the kinds of disease leading to such damage or decay of the arteries are several, each must have its own way, and its own means, of therapeutic aid. I know of no such discrimination of the kinds of arterial disease but my own ; this therefore I must use, as follows :—

1. Arteriosclerosis, the effect of persistently high blood-pressures (Hyperpietic).
2. Arteriosclerosis, the effect of certain infections, such as syphilis, typhoid fever, lead, diabetes, etc. (Toxic). In many of these the blood-pressure is not necessarily or usually increased, if at all ; in others, such as lead, it is raised throughout.

3. Arteriosclerosis, the effect of senile involutionary changes (Decrescent). In this form, again, the arterial pressures do not exceed the quasi-normal increase general in later life, unless the first process supervene upon the third, as not infrequently it does, but usually for relatively short periods.

It is evident that these several processes, as they arise in different ways, must be counteracted by different methods.

Hyperpietic Arteriosclerosis (Hyperpiesia).—Here the increase of peripheral resistance, upon which the rise of pressure depends, is of obscure origin. The immediate cause is increased friction, and this can only depend upon a narrowing of the arteries themselves, or upon an increase of viscosity of the blood ; or of course upon a combination of these factors. Russell Burton-Opitz and later

* Without Bright's Disease.

investigators have shown that the viscosity of the blood varies considerably, but depends mainly on the number of its corpuscles ; on the other hand, we know also that the arteries may contract persistently over areas large enough to maintain a considerable rise in the general pressure. In health, wide constrictions are neutralized by dilatation elsewhere, as in the splanchnic area ; but we may suppose that the splanchnic may itself be the area of constriction, or the compensatory mechanism may be liable to get out of gear, or become "labile." The proximate cause of such arterial constriction may come from without, as a product of distempered metabolism, or an intoxication by reflux waste products ; that some such poisons exist, poisons which act upon the vasomotor centre or widely upon the vessels themselves, has long been suspected, and is now supported by some proofs.

Although my text is arteriosclerosis, and hyperpiesis in children is rarely protracted enough to produce this injury in young vessels, yet our outlook on the matter would be imperfect did I not at least allude to transient manifestations of excessive blood-pressure in them, for we may be dealing with processes essentially the same. Indeed, even in children, frequent or persistent morbid excess of pressure produces some static change, though it is rarely permanent. The radial artery may thicken ; but as, after some uncertain time, it returns to its normal state, the transient thickening probably consists only in a hypertrophy of the media, which, with the return of health, disappears. Children so affected are usually pasty-faced, dark under the eyes, sickly, headachy, and at one time sluggish and moody, at another fretful and excitable. Their tongues are sticky and dirty, the breath is foul, the bowels are irregular, and the epigastrium and abdomen tumid. Often, by manipulating the abdomen, squeleches, if not true splashes, are too easily elicited. In these cases the rules of treatment, empirical as they are, are promptly efficacious. The diet must be restricted, particularly in respect of fats, sugars, meat, and strong broths. Even milk may be given too liberally in these cases, especially in its natural state ; for a child of ten years of age thus disordered, one pint, prepared in one way or another, is sufficient milk for the twenty-four hours. Indeed the quantities of food must be moderated in all directions, for the mother is too apt to stuff the child, or the school-boy to stuff himself. During the ailment, three or four rusks and a cup of milk are enough for breakfast ; a little light broth, with a biscuit, may be given in the forenoon, and at dinner some plain white fish, or chicken, with but little potato, and a light pudding. Full plates of farinaceous or stodgy puddings are to be forbidden, as flatulent and clogging to the digestion ; light steamed bread puddings, a little blanchmange, junket, and the like, are to be preferred. Tea to be as breakfast, rusks or dry toast being better than thick slices of bread. Butter is to be given scantily ; fruit, raisins, currants, jam, cakes, not at all. Some milk food will make a sufficient supper. The temperature in these cases sometimes rises a little in an irregular way ; where this is so, the food should be even more sparing for the time, and but little of it solid. When feverish, the patient must stop in bed ; otherwise he is better about, gentle exercise out of doors being allowed.

Of medicines, mercury is the chief. It may be administered as calomel or as grey powder. Grey powder is the form of which I have most experience. Under the use of fractional doses the breath sweetens, the actions of the bowels become more normal, and the stools less offensive. For a child of ten, a quarter of a grain of grey powder thrice daily may be ordered, and this in repeated periods of four or five days. The mouth must be closely watched, and kept very clean. If the drug produces two motions a day we need not hold our hand ; but if mucus becomes evident in them, the remedy should be reduced or suspended. As the tongue cleans, and the other symptoms are mitigated, a bitter stomachic

mixture may be administered. Children dislike bitters, but they are efficacious, and if pleasantly flavoured will be taken readily by well-disciplined children. They should be given before the meals. The diet may now be cautiously enlarged, but fats, sweets, and even starches are to be given with a sparing hand. These children are often of nervous stock, and their ailments may be coloured by whims and ill-humours; still, the disorder must fundamentally be one of the *primæ viæ*. When thoroughly clear of the disorder, it is helpful to give these patients cod-liver oil; during the colder months of the year this fat is so well digested by the young that it may displace with advantage some of the other "rich" elements of the dietary. Under this kind of management the full sustained pulse and obtrusive artery gradually subside. This is one variety of arterial disorder; there are others for which we have as yet no explanation. Latent infections may be concerned in them. When the vessel returns to its normal tenuity I cannot say, as one loses sight of the patient before this comes about; but if some years later an opportunity arises for a re-examination, it will be found, should the amendment have been maintained, that the walls of the vessels have returned to their normal condition. The morbid alteration, as I have said, may lie in an increase of the muscular tissue only. Whether these children are more apt than others to fall into the hyperpietic disorders of later life, I am not yet able to say.

In hyperpiesia of the adult, the symptoms are probably of like nature. Unfortunately, so apt is the bodily system in adjusting itself to abnormal conditions, hyperpiesia often establishes itself in the adult without betraying its presence. Indeed, high-pressure in the cerebral vessels may give rise, for a time, to a sense of well-being. A man of middle life may report himself to be in excellent health; when, for a skin eruption perhaps or for life insurance, he comes to a physician; yet the wary practitioner may discover an arterial pressure of 160–190 mm. Hg. The radial artery may be already a little thickened, and the left heart enlarged. If the man, who had regarded himself as healthy, will submit on trust to a long, close, and troublesome medical treatment, and much irksome management of his diet and habits, it may still be possible to restore the health more or less completely. On the other hand, to continue in this disorder for some years will lead to death by apoplexy or by heart failure, even if life be not cut short sooner by an acute pneumonia.

The patient may then get rid of his plethora and his cardio-arterial strain, if he will pay the price. But at a somewhat later stage the outlook is not so hopeful; the circulation—heart and vessels—may have acquired a permanently abnormal set, and a restoration of the normal balance be no longer practicable. In such a state, to try to reduce the arterial pressures to the normal mean disturbs the artificial without re-establishing the original balance, and the treatment is not completely successful; it becomes a compromise: yet the compromise may suffice, in moderate cases, to keep the disorder at bay, to postpone or prevent an apoplexy, and to husband the resources of the heart.

Happily in these cases the heart is usually of good quality; its coronary circulation, until it is embarrassed by atheroma, is at high pressure; and even in advanced atheroma, if the progress of the disease be gradual, the nourishment of the heart, stretched and strained as the organ may be, is kept up, somehow or other, with a wonderful steadiness. The term "cardiosclerosis" is a specious ambiguity. Under it such patients are indiscriminately accused of "a weak heart," and are treated on this line. Yet these "weak" hearts are often staggering under systolic pressures of 200–240 mm. Hg! Our treatment of "weakness" of this kind cannot be that of a heart failing intrinsically under ordinary or low pressures. Enlarged such hearts certainly are, and sooner or later, if an apoplexy be averted, will be defeated; but commonly such

over-driven hearts hold on heroically. With caution, and at certain moments, the physician may use such cardiac stimulants as digitalis or strophanthus ; yet his main duty is not to spur the heart on, but to relieve it of its enormous burden. For even if recovery of the normal adjustment be past hope, much may be done to maintain for a while some degree of equilibrium.

In early and late stages of hyperpiesia the method of cure is in principle the same. In many instances the rise of arterial pressure is due to excess of food, positive or relative. The subjects of this plethora, large eaters as they may be, may not be fat, nor ruddy ; often they are so, but not a few are even lean and sallow. In others, however, the intake has not been more than many persons dispose of easily—individuals vary widely in their capacity for disposing of excess of food—but has been more than the individual capacity. Many of these persons, in both categories, if they do not present a personal history of gout, yet come of gouty stock, and are wont to regard themselves as gouty. Moreover treatment directed against the supposed gouty habit, especially a spa treatment, often answers to expectation. If the man be fat, he must gradually reduce his intake till he brings himself back near the normal weight of his earlier years—say to his weight at forty. To bring the food down gradually, even to half the quantity habitual to the individual, has in many cases the happiest results. It is found that confinement to bed for a couple of months during the severer reduction of the alimentation is efficient in moderating pressure. Alcohol alone does not seem to lead to atheroma, yet in conjunction with other causes—as, for instance, with lead poisoning—it has a strong contributory influence. The same may be true of tobacco. Alcohol therefore must be cut out, or reduced to a nominal amount—some persons find in whey a pleasant and harmless drink ; tobacco must be strictly moderated, especially if there be any cardiac arrhythmia. As regards the chief classes of food temperance should be observed, especially no doubt in respect of the nitrogenous, and of those which contain purins. But in most cases the main purpose is the restriction of the whole intake. Certain persons, however, are so little able to convert, normally and completely, even moderate quantities of food, that an abstemious diet fails to avert or to dissipate pressures morbidly high. Some of these patients are indeed of sedentary habits, such as well-to-do ladies and closet students, for whom ordinary quantities of food are relatively excessive, or whose excretory functions are sluggish. Although Chittenden's researches suggest that mental work makes a remarkably small demand on food, yet, unfortunately, sedentary mental work in towns seems to create a false sort of appetite. The standard of the real needs of the body must, more or less, be regulated by the scales ; but in spare persons who are not free feeders we must be guided by the progress of the case, and by clinical observation. As in eating, so in the swallowing of liquids, many persons are prone to excess. Thirst, like the appetite for food, acquires strength by indulgence ; and the practice of moderating the consumption of fluid is often a good one. Coffee and tea, which raise arterial pressure, should be used discreetly.

To turn now to the fate of the food : we assume by the abiding high pressure that metabolism is imperfect or perverse, or that its organs are under strain, or that waste proteids or their amines or other results are reabsorbed. Although it is an error to suppose that an annual six weeks' cure can take the place of a systematic, patient, and persistent regimen, yet from spa treatment, as for instance at such resorts as Harrogate, Carlsbad, Marienbad, Homburg, very striking results are to be obtained. The choice of the spa and the course of the cure must be adapted to the individual case. A course of waters, with the customary concurrent precautions, can however, with a certain decision of purpose, be carried out at home and repeated from time to time as the symptoms and the functions of bowel and kidney may indicate. Of single drugs in these states,

none is to be compared with mercury, especially—for those who tolerate it well—calomel ; for others, blue pill. The calomel is to be given in fractional doses, say $\frac{1}{4}$ gr. or a little more, once, twice, or thrice daily for four or five days ; the course to be repeated from time to time. The patient soon learns when to repeat the course, and recognizes the benefit to be had from it. In the intervals, small frequent doses of podophyllin— $\frac{1}{10}$ to $\frac{1}{4}$ gr. thrice daily—of euonymin, or of iridin, may be prescribed. From day to day some notion of the effects may be guessed at by the finger, but the blood-pressure should be measured at least once a week.

Of venesection for hyperpiesis I have some increasing knowledge. I have had under observation for some years three patients who are bled at least twice a year. They look forward eagerly to the operations, and declare that the symptoms of excessive pressures are marvellously relieved by them. The same good effects I have witnessed, in a more occasional way, in patients seen and then lost sight of. A permanent improvement seems to be thus maintained ; but those three cases were beyond the stage of cure, though not of substantial amelioration. In such instances, which they recognized by the tight pulse, our forefathers were wont to take blood freely and periodically, and I believe with great benefit.

Vasodilator drugs, when the pressures are acute and urgent, have some, but not a predominant, part to play. To prescribe them continually is, I am sure, a mistaken practice. Sodium nitrite is effectual, but is not easy to prescribe, and is so variable in standard that although at one time a small dose may seem too prompt in its effects, at another a dose three times as large may seem inert. Where symptoms seem to call upon all our resources we may prescribe this drug with a few grains of potassium nitrate ; potassium iodide is incompatible with it. But it is rather by mercurial alteratives—the good effect of which is so well and quickly felt as often to provoke exclamations of gratitude from these patients,—saline laxatives, and a modified diet, that we shall succeed in alleviating the heavy stress on the whole arterial tree. Calcium salts have remarkable physiological effects both positive and negative, but we know too little of their ways to guide us in their use. It is generally desirable in cases of high pressure to regulate the ingestion of chloride of sodium ; sometimes even to withdraw the salt for two or three days. Thyroid extract I have tried perhaps inadequately, at any rate with no great success. My doses may have been too small.

Diaphoretic methods, at first sight likely to be useful to such patients, are, in my experience, disappointing. I have tried hot-air baths, such as the “ Turkish,” hopefully, carefully, and perseveringly ; but they neither give relief to the patient (often indeed they cause discomfort), nor establish any abiding reductions of blood-pressure. Now I do not use them, nor any other baths. The “ Nauheim methods ” are not generally required in these cases ; the heart, if it can have fair play, is good enough ; nevertheless, in occasional cases, after reducing the mean blood-pressures, baths and exercises and digitalis may be of use in helping the heart back to more normal diameters. Emphysema of the lungs, more frequent in the decreascent class, may add to our difficulties in hyperpiesia.

When the patient has begun to suffer from cardiac dyspnoea, and dilatation is advancing towards mitral regurgitation, we must recognize the unwelcome truth that the heart is undergoing defeat ; a substantial and permanent restoration of cardio-arterial balance is not then to be hoped for ; on the contrary, fall of pressure by heart failure is to be feared. Then the pulse usually rises in rate. Something may yet be done, but too many leaves have been torn out of the book. Diuretics such as theobromine have their value, especially when the urine is of high specific gravity, scanty, and lateritious. The class of patient now under discussion does not present the nausea, headache, epistaxis, retinal changes, and

other symptoms of Bright's disease ; but polyuria and some albumin. without granular casts, are frequent features.

It is then in the first stages of the malady, in sound subjects, when the abnormal pressures are not of long standing and the consequent ill-effects upon the heart and vessels are incipient, or even yet to come, that cures are to be made. Periods of from five to ten years, according to morbid incidence and individual equation, may elapse without permanent strain. In the curable stage, unless the peripheral resistance be unusually high and obstinate, there are better methods for the restoration of the circulation than artificial baths and exercises ; namely, natural exercise. In such cases—and we should now be catching them earlier and earlier—patients are to be encouraged cautiously to take more and more exercise. When the heart has been relieved of stress, and is pulling itself together, gentle games may be recommended, especially such as do not require sudden efforts. Gentle cycling on the level, quiet walking, even up the lower hills, golf, and so forth are useful. The efforts of tennis, even of the lawn variety, are too sudden. It is of enormous advantage if we can throw open the vast muscular areas of the blood currents, thus lowering resistance and washing away impurities. Then, if all goes well, for patients disposed to recurrent hyperpiesia, but in whom the vessels betray as yet no considerable signs of lesion, there is no medicine like regulated hill-climbing. When a healthy man essays to climb a hill, he will find that, during the first two or three minutes, the radial artery maintains its calibre ; so probably do the chief arterial areas in the body. During this period, exertion tends to raise the pressure, embarrass the breathing, and throw additional stress upon the heart. But on cautiously proceeding, the radial artery dilates, not gradually but rather suddenly, perhaps to twice its lumen ; this signifies, no doubt, the opening of other large arterial areas also ; therewith pressure falls, and the respiration relaxes ; we get, as the phrase goes, our “second wind.” During the initial period no precaution can be too great ; but after this expansion the walker will proceed with more and more ease. How far this searching but efficient method may be applicable to a particular case must depend on the discrimination of the physician. Every person from the age, let us say, of forty-five, would be wise to have the arterial pressure measured every four or five years ; oftener, if it be found above the mean for the period of life, or if morning depression of spirits, disturbed sleep, constipation, biliousness, or other vague feelings of disorder suggest that the exchanges and discharges of the body are falling short of perfection. Upon him who comes of a family in which gout or apoplexy has appeared such counsels are the more incumbent.

For cases too far advanced for natural exercise, as indeed for the initiatory stages of milder cases, massage is very useful ; more useful, perhaps, than artificial exercises. If not done rudely, but with a gentle, patient manipulation, the muscular areas are opened, and stagnant humours expelled. Probably the flow of lymph is favoured and accelerated. Warmth and massage may be directed especially to the splanchnic area. Oliver recommends the Aix douche-massage, followed by a needle bath of alternating temperatures, and warm pack. Hydropathy, carried out vigilantly and scientifically, as on Winternitz' principles, is probably very useful in high-pressure cases. Personally I have little experience of these methods ; we seem to have little scientific practice of the kind at home, and German ways of life are unsuited to the habits of most of our countrymen.

Of the effect of the high-frequency current in reducing excessive arterial pressures I have now considerable, if second-hand, experience. In many cases in which it has been tried for me, I have been led to think it had a good and abiding effect in this direction. Until diastolic blood-pressures are more systematically measured by therapists, their reports will be incomplete ; but in some of my cases these methods have been carefully observed. Dr. Lewis Jones, who has

also obtained relief in high-pressure cases from high-frequency currents, attributes the relief to "diathermy." The "dosage" of the current is of great importance; probably the doses in general use are too weak. No other form of electricity is serviceable.

In respect of climate in hyperpiesia, I have little to say which will not be supplied by the common sense of the reader. In high-pressure cases it is well, as a rule, to advise the patient not to exceed altitudes of 3000 ft. at most; but in vigorous and undamaged subjects with a proclivity to high arterial pressure, who can gradually be trained to hill-climbing, the heavy sweating in the dry evaporating air of the Alps has a remarkable effect for good. Even in these cases, however, brief stages at lower altitudes should intervene. It is in the involuntary form of arteriosclerosis that mildness and equability of climate, as in the Riviera, are specifically important.

Not a few cases in the early stage of hyperpiesis are diagnosed falsely as "neurasthenia"; but a close examination of the heart, and a measurement of the arterial pressures, should relegate them to their proper categories.

When, at last, the heart is worn out by the intolerable stresses under which it has been permitted to suffer; when it yields in its walls, leaks at its valves, and is giving up the unequal strife, the treatment falls into line of like events arising from primary diseases of the heart, which are described elsewhere in this work.

Toxic Arteriosclerosis.—It would be impossible to enter upon the infinite methods of treatment of the various infections which may issue in arteriosclerosis. It is presumed that the arteriosclerosis of syphilis is more likely to supervene in cases in which specific treatment has been neglected or perfunctory, and the best must be made of a belated effort. Salvarsan may prove to be of invaluable service in syphilitic diseases of the aorta and of the peripheral (e.g. cerebral) vessels. For other distempers, too often we have no direct antidote; the cure must be indirect. In the arterial disease of typhoid fever, for instance, the patient must, if possible, be restrained from the full use of body and mind until, presumably, the poison is eliminated and neutralized. The long survival of the specific bacillus in these patients is now well-known. We have as yet little knowledge of the ultimate history of such cases. My impression is that in these arteriosclerotics life is not so much abbreviated as impaired in its energies. In most of the toxic cases the blood-pressures are not raised, and we have not this guide to the degree of disease or amendment. Similar considerations apply to the arteriosclerosis of diabetes, or of lardaceous disease, in which, again, there is no rise of pressure. In those toxic cases, such as lead poisoning, in which the pressure is raised, the sphygmometer is of course of much service.

Decrescent Arteriosclerosis.—Although, in this change, hyperpiesis is not a characteristic factor, we must beware of its intervention. It is unnecessary to insist upon the peril of any considerable rise of arterial pressure in subjects whose vessels under ordinary pressures are already decaying. Of the causes of decrescent arteriosclerosis we are in ignorance. Of its incidence and various dietetic and climatic conditions we have no trustworthy records, and consequently no inferences as to regimen. It may be that, in Sir W. Osler's words, bad tubing was used in the making up; and it is probably, like hyperpiesis, hereditary. It has nothing to do with gluttony; so far from originating in overfeeding, decrescent arteriosclerosis is prone to occur in hardworked and underfed or ill-fed persons. It is very common in workhouses, and is very prevalent, at least in the arteries of the limbs, among labourers who have not the means of excess, and have been exposed to vicissitudes of weather. Some of the cases may be ultimate stages of poisons, extrinsic or intrinsic. I find no evidence that care and anxiety, which seem to produce hyperpiesis, give rise to involuntary arterial

disease ; it appears alike in the poor and in persons of easy and happy circumstances. As life advances, pressures slowly rise, even by some 20 mm. Hg ; and if they become relatively excessive the tunica media is strained. In decrescent arteriosclerosis we must prevent or remove attacks of hyperpiesis, from which these patients are no more immune than other people ; but in involutionary cases intercurrent plethora may be dissipated as it is in the first stage of hyperpiesia ; and in practice the cases may nearly always be interpreted as of one or the other kind. Bright's disease is not essentially, nor even frequently, associated with it, deformed as the kidneys, and most other parts and organs, may be by fibrosis.

Grotesquely distorted and extensively calcified as these decrescent arteries become, treatment, seeing that the causes are unknown, is as yet very far from systematic. Iodide of potassium, even if useful in hyperpietic cases, can be of little service in the senile. The consequences are not those of the hyperpietic form. Such patients do not die of apoplexy, not, that is, in its sanguineous mode. In the involutionary disease the arteries become less and less pervious, and the peripheral parts, as they lose irrigation, fail more and more ; but these events deprive the sufferer rather of the value of life than of life itself. Like the rest of the organs, the heart is more disposed to deteriorative than to hypertrophic alterations, and so is less apt to burst the vessels. Thus, decrescent arteriosclerotics often survive to great and even to extreme old age. On the other hand, the disease may appear and advance rapidly in comparatively young persons, even in the fourth decade of life. Treatment, then, in these cases, has to concern itself rather with nutrition and economy than with depletion. By adapting the diet to a diminishing output of bodily work, by providing for the best assimilation of the simpler foods, by the addition from time to time of ferruginous and other tonics, by gentle exercises in fresh air, by mild winter climate, and by the relaxation of work and care, but by encouragement of a proper activity of both mind and body, and dissuasion from elderly indolence, the tendency to this degeneration is to be counteracted ; that is, by a restorative strategy as patient as the morbid proclivities themselves. Fibrolysins and decalcifying agents have been suggested, but in so far as they act as such they would act injuriously in dissolving the protective framework of the vessels. Of antisclerotic serums and salts I know little, and expect nothing. To exclude calcium from the food seems futile, and probably is so ; this secondary deposit is harmless, and perhaps a stopgap.

To sum up : Involutionary arteriosclerosis is incurable. The toxic forms of arteriosclerosis seem to undergo some mitigation in time ; syphilis apart, we have few specific means of cure. The use of vaccines may come hereafter ; meanwhile we must promote the excretions and prevent the engendering of toxins. As life goes on, these cases may merge into the involutionary form. It is in the hyperpietic form that treatment is most efficacious. If this malady be discovered before it has impressed itself indelibly on the vessels, we may wholly drive it away, or by no very irksome watchfulness dispel it again and again : even if we do not detect it till a later stage, we may still control it for good, or at worst postpone or possibly avert its extremer perils.

Acute and Chronic Thoracic Aortitis.—Of the treatment of chronic aortitis, or again of atheroma, there is not much to say beyond that of the general diseases of which it is a part. In fact, unless it be in syphilis, it is rarely directly cognizable until it has attained such dimensions as to be more or less irremediable. Indeed, too often in syphilis when a chronic aortitis reveals itself to the clinical observer, it has issued in aneurysm or large anfractuous (Hodgson-Welch) dilatation. In this stage it is difficult to convince oneself that specific remedies have still a

cardinal efficiency. Subacute aortitis, as such or as a phase of more chronic changes, is more frequent than is generally supposed; if the attention be awake to the crucial symptoms, the diagnosis is not difficult. Its acuter forms are most frequent in syphilis, influenza, and rheumatic fever; they must be anxiously watched for and treated by absolute rest. In syphilis also, the state of the arterial system and of the aorta should be closely watched, and specific treatment actively resumed on the appearance of any suspicious sign or symptom. If acute or exacerbated, aortitis may be attended by angina pectoris; in the chronic degree a slighter "stenocardia" may present itself. Pain about the middle or upper sternum, especially if passing down the arms, aggravated by exertion, meals, emotion, and whatsoever excites the circulation, should be promptly recognized. If not averted the disease is prone to invade the aortic valve also.

The first condition is rest, for a time as absolute as possible. As perpetual bed, for weeks and weeks, depresses both animal and mental spirits, it is a great advantage to order the rest, after sanatorium methods, in the open air. Gentle massage should be tried before the patient is released from his couch. Thus the appetite and general metabolism are encouraged. Besides the vigilant use of alteratives, gentle laxatives, and other means of securing continuous clean running of the circulation, vasodilator drugs must be used not infrequently so long as effort is attended with substernal discomfort. Erythrol tetranitrate or nitrite of sodium may be used in appropriate doses. Exacerbations of the pain are often attended by some rise of temperature for a day or two, especially in cases of rheumatic fever, indicating the inflammation at work within; but beyond the rest, this slight aortic fever may not need special treatment. All cares of life and business must be resolutely excluded. Digitalis and other drugs reinforcing or accelerating the circulation must be avoided. Meals must be light and unstimulating, and, if frequent, very moderate in quantity. Iodide of potassium is to be administered throughout the illness; but unless there be evidence of syphilis, 5 gr. three times a day is sufficient. In rheumatic cases, of course, the salicylates also will be needed. In men of middle life syphilis is the most frequent cause, and must be detected, and by the usual specific means combated, as promptly as possible.

T. Clifford Allbutt.

ARTHRITIS DEFORMANS.—(See RHEUMATOID ARTHRITIS.)

ARTHRITIS, SUPPURATIVE.—When once a joint cavity has become full of pus, the first principles of treatment are free incisions into the joint, and drainage. These incisions must be made at points most *accessible and convenient*: accessible, so that important structures around the joint be not injured; convenient, so that drainage be favoured. In the knee-joint, for example, convenience is sacrificed to accessibility, since, while drainage through the popliteal space is very efficient, there would be great danger of injuring important structures, and the joint would have to be flexed to keep a tube in position. It is, however, occasionally possible and advisable to pass a tube through the joint to the popliteal space; the posterior opening must be made at the side of the vessels.

After the pus has been evacuated, the joint cavity should be irrigated with a weak antiseptic, peroxide of hydrogen being the best for the purpose. Some authorities recommend the application to the synovial membrane of pure carbolic acid, followed by absolute alcohol, after a free exposure of the joint. We cannot recommend such drastic treatment. After operation the limb is to be fixed on a splint, or by some suitable apparatus, in a position that will be best for the patient should ankylosis ensue, e.g., the foot at right angles to the leg in cases of disease of the ankle-joint.

If the case does well, the tubes must be removed at the earliest possible moment, in mild cases within forty-eight hours ; and as soon as it is clear that the acute inflammatory phenomena have subsided, massage and passive movements may be undertaken. We would point out that, contrary to what is often stated, a considerable amount of movement may be regained in these cases, if an operation is performed early, and if drainage is not prolonged. At the same time, this treatment requires the greatest care and discrimination, and if movement is followed by pain, swelling, and rise of temperature, it must be stopped.

In more severe cases it will be necessary to retain the tubes for a longer period, and if the joint has been extensively destroyed there is little hope of any result beyond ankylosis. In the worst cases, where the bones are damaged and constitutional symptoms are severe, or where previous drainage has failed, excision or amputation will be required.

Excellent results have been obtained by the use of Bier's method of passive congestion (q.v.) in cases of suppurative arthritis. W. H. Clayton-Greene.

ASCITES.—(See CIRRHOSIS OF LIVER.)

ASTHENOPIA.—The symptoms of pain in or about the eyes, headaches following the use of the eyes, or the running together of print when reading, should lead to a careful examination of the eyes. Organic disease, either of the media or fundus, must first be excluded. (*N.B.*—The conjunctiva should be looked at critically for signs of any chronic inflammation, especially of follicular conjunctivitis, and astringents ordered if necessary.)

1. The refraction should be tested, and the correction for any hypermetropia, myopia, or astigmatism given. If the headaches are experienced both in distant and near vision, the correction of any hypermetropia or astigmatism should be worn constantly. Myopes may prefer their distance correction for general use, but if they have asthenopic symptoms they are usually more comfortable for close work either (1) with an under correction, or, (2) when the myopia is less than 3D and equal in the two eyes, with no glasses at all.

2. The external muscles should be tested for *insufficiency* with the Maddox rod. If there is *exophoria*, a prism with the base inwards is often of great assistance for close work. With *hyperphoria*, a vertical prism slightly under-correcting the defect may give invaluable help. It must be remembered, however, that only a small proportion of the muscle defects which are found give rise to symptoms, and therefore it is only these which call for correction. It is a good rule, where glasses have not previously been worn, to order at first the lenses correcting the refraction error alone, and to add the prisms at a later date if the asthenopic symptoms have not been alleviated.

3. The general health of the patient is a very important factor, and should be carefully looked into and treated, especially in regard to anæmia, constipation, and neurasthenia.

4. The conditions of work must also be attended to. See that the head is kept in a proper, upright position ; that the work is held well away, not nearer than 14 inches ; that there is good illumination coming from the left side ; and that, when reading, good print is used. W. Tindall Lister.

ASPHYXIA.—(See DROWNED, TREATMENT OF THE APPARENTLY ; LARYNGEAL OBSTRUCTION ; POISONING.)

ASTHMA, BRONCHIAL.—Asthma arising as the result of heart or renal disease will be dealt with under those headings. Idiopathic or bronchial asthma will be considered here.

It has been abundantly shown, by experiment, that bronchial asthma can be produced by spasm of the bronchial tubes, though there are still many who believe that in some cases the symptoms are produced by a rapidly oncoming œdema of the bronchial mucous membrane, a sort of urticaria of the bronchial tubes. Moreover, it is evident that, although everyone possesses the mechanism for the production of asthma, only a few suffer from the spasm; and that therefore there must be an underlying sensitiveness to stimuli capable of acting on this mechanism in the asthmatic.

Treatment has consequently turned upon :—

(1) *The attack or spasm* (or œdema); (2) *The underlying tendency*; (3) *The removal of the cause*.

1. The Treatment of the Spasm.—To give a complete list of all the remedies which have been reported as successful in the treatment of this complaint would be confusing. There is probably no condition in which so many drugs have been used; and it must be said, at the outset, that a remedy which is immediately successful in one case may have no effect in another, and further, may prove quite useless in the same case at another time.

Morphia we should place first, as of most value for the rapid relief of the distressing dyspnœa, and its effect is often increased by the addition of atropine. These should be given together in the form of a hypodermic injection (morphia $\frac{1}{6}$ – $\frac{1}{3}$ gr., atropine $\frac{1}{120}$ – $\frac{1}{60}$ gr.).

Caution.—Morphia should not be given where there is considerable bronchitis, or in old people, and on no account where there is kidney disease. The danger of the formation of the “habit” must be borne in mind, and for that reason it is important not to leave the treatment in the hands of the patient; and if the case is one where the attacks are of very frequent recurrence, and the necessary dose has to be increased, it would be wise to seek a less risky means of relief.

Inhalations and fumigations have been largely used. Chloroform is often very efficacious, but the relief is generally very transient. Much the same may be said of ether. These are remedies which should never be left in the patient's own hands. Nitrite of amyl, in some cases, gives temporary relief (it is well to remember that less headache will follow its use when it is inhaled through the mouth instead of through the nose). Much more generally useful and more lasting in their effects are the inhalations of certain fumigations. Tobacco is successful in some cases (when not used habitually). Nitre paper is perhaps one of the commonest remedies, and often gives early relief; it must be used freely so as to make the air of the room dense with its fumes. Many papers are used which contain, in addition to nitre, numerous other drugs, such as the iodide and chlorate of potash, and powdered digitalis, stramonium, and lobelia leaves.

Powders containing lobelia, nitre, green tea, and stramonium are very useful in many cases. Cigarettes also are made containing any of the above-mentioned drugs, and arsenical cigarettes are found to give relief in some instances. With these remedies the dose has frequently to be increased, they often leave bad headache, and, moreover, they sometimes seem to irritate, or at any rate increase, any attendant bronchial catarrh. The fumes often irritate and cause fits of coughing even when they give relief. Asthma is a pulmonary neurosis, closely allied to other neuroses, frequently met with in families in which other members suffer from migraine and allied affections. It is, therefore, not surprising to find many remedies which are of service in the treatment of migraine equally so in cases of asthma. Thus, strong tea (or Guarana tea), coffee, or, better, citrated caffeine, phenacetin, phenazone, and acetanilide, will, one or other of them, sometimes act like a

charm. Of this class of remedies it must be said that they frequently lose their power, and it will often be found that where they relieve the spasm, their use is attended by great sleeplessness: in some cases, sleeplessness alternates with asthma, and is a most difficult symptom to combat. Alcohol must be mentioned as a remedy, because it is often so quickly efficacious. The objections to its use are obvious, especially when the attacks are frequent.

Lastly subcutaneous injections of some preparation from the suprarenal gland have been found very successful in cutting short an attack. Whether its action is by preventing the (theoretical) œdema of the bronchial tubes, or by blanching the nasal mucous membrane, or in some other way, is not decided. However it acts it is a treatment that can be recommended—5 to 15 mins. of 1-1000 adrenalin chloride solution to be injected subcutaneously as soon as the attack commences.

Lastly, the induction of vomiting, or at least nausea, is often attended by instantaneous relief of the spasm. Tartrate of antimony and potassium, gr. $\frac{1}{25}$ in water, every half hour till nausea is produced, is perhaps the best of such remedies. Sometimes the relief may be due to the emptying of an overloaded stomach, which has acted as a cause. Some patients will bring on vomiting by tickling the back of their throat, or it may be produced by an ordinary emetic.

2. For the Underlying Tendency.—The actual attack having passed off, it becomes necessary to lessen the frequency of its return, by reducing the sensitiveness of the mechanism to outward stimuli. Many of the remedies mentioned under this heading will be found useful even during the attack, but their chief aim is directed towards permanently curing the patient, or at any rate lengthening the period of freedom from attack. The two drugs which are found most generally useful are iodide of potash and arsenic. They can be given separately or together, but in any case a prolonged course is advisable. Some patients, who are very intolerant of the iodide, will stand arsenic well, and the prescription of bismuth with the latter will often prevent the gastric irritation so frequently seen as a consequence of its administration. Opium, belladonna, and lobelia are also of service as preventives, and are generally given in combination with arsenic and potassium iodide. Several cases have been permanently cured by the application of electricity to the neck: it is supposed that the current blocks the vagi, and so prevents the conveyance of irritating stimuli. What has been called the pneumatic treatment, elaborately carried out at Reichenhall and Meran, certainly materially benefits a large number of chronic cases. Briefly, the treatment consists in alternately inspiring compressed air and expiring into rarefied air. It is of little use in the acute condition, but where, as the result of repeated attacks, bronchial catarrh and emphysema have resulted, it is most useful.

Of all the preventive treatments so far mentioned, undoubtedly the greatest reliance should be placed on a prolonged course of arsenic and iodide.

One is sometimes asked what inoculation treatment is to be recommended for asthma. There is none that can be relied upon for the attack itself. As a possible preventive treatment one would say this: In a certain small group of cases catarrh is a common cause; whenever the patient gets a "cold" an asthmatic attack is liable to supervene. In such cases it has been suggested that, in order to lessen, or prevent, the tendency to catarrh, vaccination with *Bacillus catarrhalis* should be performed.

3. Removal of Cause.—There is, perhaps, no disease in which the removal of the cause is so immediately attended by the subsidence of all symptoms. One admits the difficulty, in many cases, of fixing on the true etiological factor; also that, in others, any of several causes may be sufficient to start an attack; nevertheless one is convinced that, in the majority of cases, a definite cause,

or causes, can be found, and their removal be attended by the most beneficial results. In one it may be a chill, the slightest bronchial catarrh being accompanied by asthma; in another it may be an overloaded stomach or bowel, or some other source of peripheral irritation, such as worms, teething, or skin troubles. Asthmatic attacks are seen in gouty people when they are most gouty, and so forth. But of all causes, those which are found in, or come through, the nose and throat, are the most likely to give rise to attacks. It therefore becomes essential that the curative treatment of asthma should commence with a careful search for the cause. The nose, mouth, and throat should be examined for adenoids, rhinitis, enlarged tonsils, delayed and painful teething. Careful notes should be kept by the patient, or friends, as to the circumstances which give rise to the trouble, so that, by a process of exclusion, the true cause may be discovered. These causes are very various, the smell of birds, cats, dogs, horses, certain flowers, fumes, dust, etc., having all at one time or another been shown to initiate an attack.

General and Climatic Treatment.—Asthmatics are generally very susceptible to climatic influences. Many are always free in large towns, others only in country districts or at the seaside. Curiously enough, a sufferer will sometimes be quite free from his trouble for some time after first moving into a fresh district, and subsequently the attacks will return, or the reverse may be the case. As a rule such patients are freer from trouble when in large towns. Moderate altitudes are often beneficial, but care must be taken not to send patients, in whom long-continued asthma has given rise to emphysema and cardiac dilatation, to mountain resorts. Indeed, where bronchial catarrh and emphysema have resulted, these call for greater consideration than the asthma, and such cases do well to winter in warm, sunny, seaside places, an equable, moist climate being the best.

From what has been said, it will have been gathered that the diet often needs careful consideration; dyspepsia must be treated and constipation avoided.

The following prescriptions are suitable for the treatment of such cases:—

FUMIGATION FOR THE ATTACK.

R Pulveris Belladonnæ Foliorum	Pulveris Stramonii Foliorum
Pulveris Hyoscyami Foliorum	Potassii Nitratis aa Partes Æquales

M. Half a teaspoonful to be burnt for each fumigation.
(*Vict. Park Hosp. Pharm.*)

R Stramonium Leaves	aa 3iv	Lobelia	3iss
Green Tea			

Mix, and pour on the mixture enough saturated solution of nitre to wet it. Dry it and keep in closely stoppered bottle. (*Plant.*)

R Daturæ Tatulæ	Pulveris Potassii Nitratis	3ij
Stramonii Foliorum	Olei Eucalypti	3ss
Cannabis Indicæ	aa 3ij	

Mix thoroughly. (*Woodward.*)

ANTI-ASTHMATIC MIXTURE.

R Potassii Iodidi	3ij	Tincturæ Hyoscyami	3iv
Liquoris Fowleri	3j	Aquæ Chloroformi	q.s. ad 3viij
Vini Ipecacuanhæ	3ij		

M. ft. mist. A tablespoonful in water three times a day after food. (*Whitla.*)

MIXTURE FOR ASTHMATIC PAROXYSM.

R Tincturæ Lobeliæ Ætheræ (B.P.)	℥xv	Spiritus Ammonię Aromatici	℥xx
Potassii Iodidi	gr v	Syrupi Tolutani	3j
Potassii Bromidi	gr iv	Aquæ Camphorę	q.s. ad 3j

ANOTHER DRAUGHT FOR PAROXYSM.

R	Tincturæ Cubebæ	℥v	Tincturæ Lavandulæ Co.	℥iij
	Ammonii Bromidi	℥ij	Spiritus Chloroformi	℥iss
	Spiritus Ammoniaë Aromatici	℥ij	Aquam	ad ℥vj
	Spiritus Ætheris	℥iss		

One-sixth part for dyspncea.

ANTI-ASTHMATIC PILL.

R	Sodii Arsenatis	gr ʒ $\frac{1}{2}$	Extracti Belladonnæ	gr $\frac{1}{2}$
	Extracti Nucis Vomicaë	gr j	Extracti Gentianæ	q.s. ad gr iij

M. ft. pil. One pill twice daily after food.

W. J. Hadley.

ATHEROMA.—(See ARTERIOSCLEROSIS.)**BACKWARDNESS.**—(See MENTAL DEFICIENCY IN CHILDREN.)**BACTERIOTHERAPEUTICS.**—(See SPECIFIC THERAPY.)

BALANITIS.—By balanitis is meant, strictly speaking, inflammation of the glans penis, while posthitis denotes an inflammation of the prepuce, but as the one never occurs without the other, balanitis is often used as an abbreviation of balano-posthitis. The causes may be divided into venereal and non-venereal. Of the former no further mention need be made here, except to note the difficulty and the importance of making a correct diagnosis. Bacteriological investigation may be necessary in a doubtful case. Of the non-venereal variety there are two main causes, viz., phimosis, or long prepuce, and want of cleanliness. If the prepuce cannot be retracted, the parts cannot be adequately cleansed, and balanitis is almost certain to supervene sooner or later. Impure intercourse, gout and diabetes, cystitis and decomposition of the urine may be causative factors in individual cases.

TREATMENT.—This varies with the cause. Of cases due to venereal disease the treatment is given elsewhere. In the non-venereal cases the first thing to decide is whether the prepuce can be retracted fully or not, without the fear of paraphimosis supervening. If it cannot, it must be slit up, or circumcision must be performed. In very acute cases—and these are usually gonorrhœal—and when the swelling of the prepuce is considerable, the latter should be slit up to the coronal sulcus. In subacute, chronic, and recurrent cases, circumcision is to be preferred. In gouty and diabetic patients circumcision should rarely be resorted to, and then only with the precautions mentioned under PHIMOSIS.

In all cases frequent cleansing with boracic lotion, and the application of a strip of gauze or lint wrung out of lead lotion to separate the adjacent inflamed surfaces of the glans and prepuce, when the latter has not been removed, will effect a cure. In chronic cases in adults the urine should always be examined. In gouty and diabetic cases appropriate dietetic and medicinal treatment is called for. In the diabetic form Thomson Walker recommends the use of powders—boric acid, starch, and zinc oxide—and the use of zinc oxide ointment to the skin of penis and scrotum, which is often affected by eczema.

H. A. T. Fairbank.

BALDNESS.—(See HAIR, DISEASES OF.)**BANTI'S DISEASE.**—(See SPLENIC ANÆMIA.)**BATHS.**—(See HYDROTHERAPY.)**BELL'S PALSY.**—(See FACIAL PARALYSIS.)

BERI-BERI.—The main dangers arise from cardiac dilatation or paroxysms (cardiac crises) resulting from the paralysis of the vagus.

TREATMENT.—Complete rest in the recumbent position. Nutritious food in small quantities at a time, and similar restriction in the amount of fluid given at a time, in order to avoid embarrassment of the cardiac action from dilatation of the stomach. Rice and other bulky forms of food must not be given on account of this liability, with the addition in the case of rice that in some kinds of rice a deficiency of some substance, "vitamine," contained in the outer portion of the grain, seems to be the cause of the neuritis. Beans, yeast, and substances prepared from the millings of rice are probably of some benefit in remedying this deficiency. Adrenalin is claimed to be of advantage by some. In cardiac paroxysms, amyl nitrite, capsules of 5 min., or nitroglycerin tabloids, $\frac{1}{100}$ gr., should be used, and in extreme cases venesection may be advisable. Strychnine at this stage, hypodermically or otherwise, may be required.

The bowels must be kept freely open with saline aperients. Sodium sulphate, 1 dr. every morning, will usually suffice. Removal of the persons from the locality in which the disease was acquired is by many considered an essential.

When the more acute symptoms have subsided and the danger of sudden cardiac dilatation is over, graduated exercise may be allowed. In cases where paralysis is complete, care must be taken to avoid contraction of joints. When the "foot-drop" is extreme, a cradle should be used to prevent the weight of the bedclothes increasing the deformity. If it is already established, splints may be necessary. Strychnine should be avoided in the early stages, and faradization and massage employed only when all acute symptoms, including muscular tenderness, have subsided.

C. W. Daniels.

BERNHARDT'S DISEASE.—(See NERVES, PERIPHERAL, AFFECTIONS OF.)

BIER'S HYPERÆMIC TREATMENT.—Artificially-produced hyperæmia as a method of treatment was introduced by Professor Bier in 1892. Its object is to cause a hyperæmic condition of the diseased area, or to increase an already existing hyperæmia in an inflamed part, and thereby to aid the living tissues in their struggle against microbic invasion, in the belief that a sensible increase in the volume of the blood circulating through an inflamed part is, owing to the antimicrobial action of the blood, a real help to the tissues in their contest with the invading micro-organisms.

It is of the first importance that the blood continue to circulate. Any stasis of the blood-current would inevitably be productive of harm, as it would diminish the resisting power of the tissues in a chronic inflammatory condition, and, in an acute inflammation, would tend to cause gangrene. Too great emphasis cannot be placed upon the fact that *the blood must, throughout the whole course of treatment, continue to circulate, and that stasis must be avoided, as it can cause only harm and may spell disaster.* Therefore the duty of the surgeon is to assure himself that the blood in the part subject to treatment is circulating freely. Where the rubber bandage is employed, this is done by noting the beat of the pulse in an artery distal to the constriction. Frequently, however, owing to œdema the pulse can, after some time, barely be felt. In all cases it will be found a safe rule to regard the application of the method as satisfactory when the treatment is painless, or when, after a few minutes, any existing pain is mitigated. Should the reverse be the case, it may be taken that the constricting band or the cupping-glass is too firmly applied, and the mistake must at once be rectified.

The two essentials therefore are : (1) That the blood continue to circulate in the inflamed part, and (2) That the treatment be painless. Emphasis is to be placed

on the fact that the method, properly applied, is entirely free from pain, and that, if pain be present prior to its employment, this symptom should be mitigated within a few minutes. The application should be painless and the patient should look forward with satisfaction to its renewal.

Of the five cardinal signs of inflammation—heat, redness, swelling, pain, and impaired function—the hyperæmic treatment increases the first three and diminishes the last two. Its aims may be stated to be : (1) Arrest, or at least mitigation, of the infective process ; (2) Prevention of suppuration in many cases in which this is threatened ; (3) Relief or diminution of pain ; (4) Avoidance of operative treatment in many cases, or, where this is not possible, the substitution of a less severe and less mutilating operation than would otherwise be necessary ; (5) Saving of time owing to hastening the eliminating processes in cases in which suppuration and necrosis are unavoidable, as in carbuncles in their later stages ; (6) Increase in the antimicrobial action of the blood owing chiefly to the greater quantity circulating in the diseased area ; (7) Stimulation of the process of repair, as shown by the success attending its use in cases of delayed union of fractures.

METHODS OF APPLICATION.

To attain these objects three means are employed : (1) *Elastic constriction* ; (2) *Suction by means of cupping-glasses* ; (3) *Heated air*.

The first of these causes a hyperæmia which is purely passive, i.e., venous ; the second, one which is chiefly passive, though at first in part active or arterial ; the third, on the other hand, induces an active, i.e., arterial, hyperæmia.

A priori it would be imagined that the maximum of benefit would follow the employment of arterial hyperæmia, but in practice it will be found that, as a rule, passive hyperæmia is relied on far more than the active (arterial) form, and certainly yields results that are, on the whole, more satisfactory.

In the following remarks, passive hyperæmia induced by elastic constriction will receive chief attention, owing to the facts that it is the simplest method to use and that most commonly employed, as it needs no apparatus except a rubber bandage.

Suction requires cupping-glasses of various sizes and suction balls of different force. It is necessary to have available *at least* three different sizes. The method is applicable chiefly to the trunk, i.e., where elastic constriction cannot be employed.

The heated-air method is the least frequently used, as it requires a special form of apparatus which has to be made to suit each individual case, and it calls for more watchful care and attention ; for these reasons it is less employed by the practitioner.

1. **Elastic Constriction** is the oldest of Bier's methods. The best results will be obtained by using a short Martin's bandage, $1\frac{1}{2}$ to 2 in. in breadth for the upper limb, and 2 to $2\frac{1}{2}$ in. for the lower—applied to the upper arm in affections of or below the elbow, and to the lower part of the thigh where the lesion to be treated is in the knee or in a part distal to it. In affections of the head and neck, as also in scrotal, penile, and testicular maladies, a band of ordinary garter elastic answers admirably. In all these cases the constriction is applied to what may be termed the root of the part ; in all cases, of course, proximal to the seat of the affection. Unfortunately, the above comprise the only regions that are amenable to the elastic-bandage constriction. The writer has been unable to apply the principle to the hip-joint, and has been only partially successful with the shoulder-joint, where he employs the bandage over the middle of the clavicle and upon a firm pad placed in the axilla.

It is of prime importance in the employment of the bandage that *the pulse*

be felt distal to the bandage. The part undergoing treatment must be a dark, congested, bluish colour, which has in it a suggestion of red.

It is impossible to lay down definite rules as to the length of time the bandage should be applied per diem. Each case is a law unto itself. In general the aim in chronic cases should be nine hours "on" and three hours "off." In young children three hours on and three hours off may be the rule, until the part becomes accustomed to the change in its circulation. After the removal of the constricting bandage, the congested part is elevated, and the area covered by the bandage should be sponged with 80 per cent alcohol. With regard to cases of acute inflammation, experience teaches that many such will not stand so long-continued an application of the bandage, and the same applies, at the commencement of the treatment, to many chronic cases. The sensations of the patient must always be the guide, and in any case it is better at first to *underdo* rather than *overdo* the treatment. In applying the bandage it is well to make each turn cover the upper two-thirds of the turn below, in order to diffuse the constriction evenly over a large area. In affections of the hand and foot, the bandage should be applied above the elbow and knee respectively, as in the forearm and leg the interosseous veins can easily escape constriction, and thus interfere with production of the desired hyperæmia.

Should the inflammatory lesion have reached the stage of suppuration prior to the commencement of the treatment by elastic constriction, then, as in every case, it is essential that the pus should first be evacuated. Let it be clearly understood that Bier's treatment, potent as it undoubtedly is in cases in which suppuration is threatened, is powerless to effect the absorption of pus already present. The abscess, acute or chronic, must be incised, and the pus evacuated. This is, of course, of more immediate importance in acute than in chronic suppuration. Even in acute cases, however, only an incision large enough to allow the escape of the pus is required. Large incisions are not called for, and the harmful and too frequent practice of squeezing the abscess cavity, which is apt to cause laceration of the protecting zone surrounding the area of suppuration, with resulting pyogenic infection of a diffuse nature, is strongly to be deprecated. Once an abscess has been opened, even by a tiny puncture, the discharge, when Bier's bandage is employed, is usually free, and the mitigation of symptoms due to septic absorption is quickly and pleasantly attained.

The writer has employed Bier's elastic bandage most frequently in cases of *tuberculous disease* of the elbow, wrist, bones and joints of hand and foot, knee, and ankle. In such cases results have been obtained far surpassing those he has observed with any other method of treatment. It must be admitted that in almost every case of tuberculous disease of the above joints, injection into the joint cavity of a sterilized 10 per cent emulsion of iodoform in glycerin has been employed at the same time as elastic constriction. It is a matter of difficulty, therefore, to assign the proportion of credit due to each measure. Each is of real value, and in combination they certainly offer the best chance of cure open to us in early tuberculous disease of these joints.

Among other conditions in which the constricting bandage has been usefully employed may be mentioned: *Whitlows* of all types, with or without incision to evacuate pus; *Suppurative arthritis* of elbow, wrist, knee, and ankle, after incision; *Chilblains*; *Septic injuries* of all descriptions to upper and lower limbs accompanied by *lymphangitis* and *cellulitis*; *Osteomyelitis* of the bones of the upper and lower extremities of pyogenic and tuberculous origin; *Tenosynovitis* of pyogenic, tuberculous, or gonorrhœal origin; and *Gonorrhœal arthritis*, especially of the knee in the male, and of the wrist-joint in the female. The above list makes no pretension to be exhaustive. It merely comprises the indications most frequently met with in the practice of the writer. With

increasing experience of the method, the practitioner will probably come to the conclusion that it is of benefit in the larger number of affections of the extremities which come under his care.

In the treatment of septic conditions of the head and neck, the employment of a collar of garter elastic round the lowest part of the neck has yielded excellent results. Many cases of infected scalp wounds, of erysipelas of the head and face, of boils and carbuncles, have thus been benefited. In tuberculous adenitis of the neck, and in lupus of the face, the results have generally been comparatively disappointing.

In gonorrhœal and tuberculous epididymitis good results have been obtained.

In cases of acute inflammation, the cutaneous redness frequently extends several inches higher up the limb than was the case prior to the application of the bandage, and may extend even to the area of constriction. This condition, alarming as it may appear to the novice, as apparently indicating extension of the inflammation and therefore failure of the treatment, or even worse, need occasion no alarm, and may be regarded as almost normal. In chronic inflammatory conditions such increase in the area of redness is hardly ever seen. In suppurative conditions, which, as above stated, always demand incision, the purulent discharge generally is increased at first but rapidly diminishes, as do also the redness and œdema.

For the first few hours after its application, the constricting bandage demands constant supervision, and in acute cases it is wise to insist upon the attendance of a reliable nurse.

At the risk of repetition the writer would emphasize that success depends upon the correct application of the bandage. Too tight constriction may endanger the vitality of the affected part, especially in acute inflammatory conditions of the fingers, e.g., whitlow. Venous congestion without arterial obstruction is to be attained. Most important of all: no pain should be caused by the application of the constriction. The patient's sensations must be the practitioner's guide, and when a patient of ordinary intelligence makes no complaint, it may be assumed that there is nothing amiss with the method of application.

2. Suction by means of Cupping-glasses (partial vacuum).—Of this method the writer has had considerable experience, though not so much as with the constricting bandage. It is employed chiefly for affections situated upon the trunk, where the constricting bandage is inapplicable. The virtues of the method are many, and its range of application is extensive; but the writer has to admit that the results have impressed him less than those obtained in the extremities by the use of elastic constriction.

In general it will be found that the more superficial the affection, the better will it react to the suction method. The treatment cannot be employed continuously.

Bier's warning is: *Do not overdo the suction; never cause pain.* The skin must assume a bluish-red colour. If the skin appears white (anæmia), the suction is too forcible.

As in the case of the constricting bandage, when pus is present a small incision—commonly a mere puncture will suffice—must be made prior to the application of the suction glass. The writer generally employs the latter for half an hour twice daily. It is employed for five minutes, then removed for five minutes in order to permit the œdema and hyperæmia to subside; it is re-applied for five minutes, and again removed for five minutes, and this process is repeated for one hour, during which time the glass will have been "on" for half an hour and "off" for the same period. It must be admitted that the tendency is to apply too strong suction, especially in cases of acute

inflammation. Here, again, the patient's sensations must be the guide. If real pain be caused, or already existing pain be markedly aggravated, the suction must be deemed excessive. The writer has observed that in some instances even gentle suction causes pain. In such he has found that a puncture into the affected part often gave vent to unsuspected pus, and enabled the suction to be applied to the entire satisfaction of the patient. Suction applied after an incision naturally causes at first a rather free escape of blood. This, however, soon ceases. Various forms of large vacuum glasses with suction pumps attached, and provided with a rubber cuff to grip firmly the segment of the limb just outside the glass jar, have been devised by Bier and his assistant Klapp. Into such chambers the arm or the leg can be placed. The writer has had but small experience of these forms of apparatus. They are necessarily costly, and different forms and sizes are required for different parts, e.g., elbow and ankle. Moreover they present, in the opinion of the writer, no real advantage over the simple elastic constricting bandage.

In all suppurative conditions in which an incision or puncture has been made, the writer has satisfied himself that, by means of the suction-glass treatment, the pathological condition has been ameliorated; the removal of sloughs, when present, has been painlessly expedited; and a healing of the lesion more rapid than is normally the case has been obtained. The method has been employed chiefly in : (1) Cases of *mastitis*, with or without incision, according to the presence or absence of suppuration; (2) *Carbuncles* and *furuncles* after incision, and in *blind boils* without puncture; (3) *Acute abscesses*, after a small puncture had been made to allow of the escape of pus; (4) The treatment of *chronic abscesses* in which the closure of a persistent sinus was the object primarily aimed at. In all such cases the treatment has yielded better results than any previously seen by the writer.

It has also been employed, though with far less convincing results, in cases of *lupus*, especially of the face; in post-operative *keloid cicatrices*; and in *otitis media suppurativa*, after incision or rupture of the *membrana tympani*, i.e., in both acute and chronic forms. In the majority of the above cases the suction treatment apparently proved of distinct benefit, and in no instance did it exercise any harmful influence.

3. Heated Air.—This method differs from the two already described in that the hyperæmia produced is arterial and not venous. Theoretically, therefore, it might be expected to produce the best results. In the writer's experience, however, it is the least valuable of the three. The hot-air chamber has been found costly, and difficult to manage, requiring unremitting supervision on the part of the medical attendant (in two cases the patients received nasty burns), whilst the results were somewhat inferior to those obtained by the other methods. It is chiefly employed in chronic cases which are the result of previous acute inflammations, where it is of value in hastening the absorption and the removal of chronic exudations and adhesions, and is also largely made use of in the treatment of neuralgic affections.

Heated air is employed by means of (a) *The heated-air chamber*, and (b) *The heated-air douche*, and it is of primary importance that the air be *dry*.

a. *The heated-air chamber*, in its simplest form, is a wooden box provided with openings, one of which has attached to it some form of cuff to embrace the limb at the junction of the segments outside and inside the box. Felt forms a useful material for the cuff, and this is provided with a string, by the tightening of which the cuff may be firmly applied to the limb. Other openings in the box serve to provide for the entrance and the exit of the heated air. Through a small opening a thermometer is inserted, which should have its bulb

in the hot-air chamber and its marked stem outside, where it can easily be seen. The source of heat is a spirit, oil, or gas lamp, or better, an electric heater. Except in the case of the last mentioned, the lamp is outside the box, and the opening into the latter is provided with an inverted metal funnel, the wide end of which is placed above the chimney of the lamp whilst the narrow end enters the hot-air chamber. Instead of purchasing expensive apparatus, a rough but serviceable heated-air chamber may be made by even an amateur carpenter. Special care must be taken in such a case to use dry wood, as otherwise resin may sweat out of the wood and burn the patient. At the commencement it is well to use a thermometer. Soon, however, the patient will learn to estimate the temperature desirable. Here, as always in Bier's treatment, the patient's sensations constitute the best index. Not only must there be no pain, but the affected parts must never feel uncomfortably hot.

In general, the writer raises the temperature in the chamber from 180° to 230°, or even to 250° F. Higher temperatures have been employed, but, for divers reasons, are inadvisable. Accidents against which the practitioner should be warned have happened. Burns, apart from those caused by resin drops, and even gangrene of the toes and fingers, have occurred. The writer has seen one case in which gangrene of three toes, necessitating amputation, resulted. It is also to be borne in mind that intense heat, e.g., 250° F., markedly diminishes the sensibility, especially in the peripheral parts, e.g., fingers and toes, and thus burns may not be recognized until after removal of the affected part from the heated air-chamber. In general, the writer has employed this method for half an hour daily. As it is inadvisable suddenly to reduce the temperature of the affected part from say 230°–250° F. to the temperature of the room, he advises that after half-an-hour's exposure to the heated air the lamp be extinguished and the freely sweating member be allowed to cool slowly for half an hour before its removal from the chamber.

b. The hot-air douche has been employed by the writer on comparatively few occasions. He is therefore unable to write concerning it from extensive personal observation. In a few cases in which he has employed the method he has made use of a large, inverted metal funnel placed under a large spirit or oil lamp. To the upper, narrower end of the funnel a metal tube (copper) has been attached by means of a universal joint. This tube, which is about one yard in length, terminates in a rose like that of a watering-pot, but with much larger perforations. In cases in which it is advisable to concentrate the heated air on a very small area, the rose is not employed. In all cases it is necessary to encase in asbestos the end of the tube which is held in the hand, or to use a glove which has been rendered a non-conductor of heat. It is a difficult matter to estimate the degree of heat. Obviously the nearer the part to the end of the tube, the higher the temperature, and *vice versa*. In general, the heat should be raised gradually by approximating the affected part to the end of the tube, and the maximum temperature that can be comfortably borne should be employed. The writer prefers to apply the heated-air douche for two periods of a quarter of an hour each, and in neuralgic affections he chooses the time at which the neuralgic pain usually commences. In sciatica, marked relief has been obtained in some cases; in more, the results have been disappointing. The best results have been in cases of neuralgia involving the nerves of the head, especially the trigeminal and great occipital nerves, and in cases of chronic osteitis, pyogenic or syphilitic in origin, involving chiefly the mastoid process and the upper ends of the tibia.

Two patients suffering, the one from chronic pyogenic mastoiditis secondary to middle-ear disease, and the other from chronic osteitis of the upper end of the tibia—the result of pyogenic osteomyelitis in childhood—have employed the

heated-air douche for more than three years, with entire satisfaction. In both the above cases operative treatment had secured only temporary relief from the characteristic boring pains in the bone.

The writer desires to draw attention to the fact that he has by no means slavishly followed Prof. Bier's directions in every detail. The above article is to be considered as embodying the experience of a British surgeon who has studied Prof. Bier's methods and has not hesitated to modify them as the result of his own experience. It is believed, however, that it deviates from his instructions in no matter of prime importance.

Herbert F. Waterhouse.

BILE-DUCTS, CATARRH OF.—The commonest affection of the ducts—catarrh of the mucous membrane—may be simple or suppurative. Simple catarrh may be acute or chronic.

Acute Catarrh (catarrhal cholangitis) is often spoken of as catarrhal jaundice. Unless very severe it is not necessary for the patient to remain in bed. The diet should be liquid at first, and gradually increased, but should remain light till complete recovery; if there be great irritability of the stomach, hot water alone should be given till it subsides. Severe pain may be treated by hot fomentations, with or without belladonna. One grain of calomel should be given at the onset; if not an actual cholagogue, it at any rate increases the bile excreted from the biliary passages.

After the first onset the bowels should be kept acting regularly by administration of Carlsbad salts or phosphate or sulphate of soda.

Attention should be directed to the cause of the catarrh; if due to syphilis, small doses of hydrarg. c. creta may be given; and in many cases not due to syphilis, small repeated doses of grey powder are useful, possibly from the action of the drug on the pancreas. The gastroduodenal catarrh present in most, if not all, cases must be treated by alkalies and bismuth, and may be benefited by giving antiseptics internally, such as carbolic acid, salol, or β -naphthol. The jaundice is often lessened by salicylates, which probably increase the secretion and render the bile more liquid, and chloride of ammonium may be given with the same object.

When improvement is setting in, it may be hastened by mineral acids and bitter infusions.

Chronic Catarrhal Cholangitis may follow on an acute attack or come on gradually from the first. It is often set up by gall-stones in the biliary passages, the jaundice in such cases being due to catarrh of the ducts rather than to the actual gall-stones; the chronic catarrh may persist after the gall-stones have been got rid of. It is often also an accompaniment of hepatitis. For treatment of catarrh arising from gall-stones, see GALL-STONES.

Chronic catarrh, apart from gall-stones, may be very persistent, the jaundice and emaciation resulting from it giving the case much resemblance to that of hepatitis or cancer, or, still more, to disease of the head of the pancreas.

It should be treated by great care in diet, fatty, rich, or indigestible foods being avoided. Small doses of mercurials, iridin, or euonymin should be given at night, and alkalies and salicylates in the day. Constipation must be overcome, and walking exercise taken regularly—with most advantage before breakfast. Such patients benefit by a course of Carlsbad waters, or, if unable to go abroad, by the Harrogate or Strathpeffer waters.

Although both acute and chronic catarrh of the biliary ducts occur apart from actual disease of the liver, they may also be associated with such of its affections as cancer and the various forms of hepatitis or cirrhosis—indeed the biliary cirrhosis of Hanot has been said to commence in an inflammatory condition of the intrahepatic branches of the bile-ducts; in such cases, although

the liver disease itself may be incurable, judicious treatment may succeed in freeing the patient from the jaundice resulting from the catarrh. The drinking of hot water and administration of salicylates and alkalies, together with small doses of mercurials, should be ordered.

Suppurative Cholangitis arises from organisms entering the ducts, either through the blood-stream in the liver, or from the alimentary canal by the biliary passages; even if suppuration first occur in the larger ducts, it will soon spread into the finer duct branches within the liver.

The treatment consists in free drainage of the biliary passages by operation.

Infective Cholangitis is a variety spoken of by some as special to the presence of gall-stones in the common duct, but more generally agreed to be producible by any cause which will allow infective organisms to enter the ducts. It is characterized by paroxysmal attacks of pyrexia, and has been called "intermittent hepatic fever." With these occur attacks of colic resembling those produced by a calculus, shivers, and temporary jaundice. These attacks appear due to an obstruction in the common duct, which as a rule allows the passage of bile, but from time to time becomes complete. These attacks may continue for years, on and off, and may terminate in recovery; but they may, per contra, lead to fatal toxæmia or exhaustion, and the treatment should, therefore, be operative removal of the obstruction when this is possible.

Sidney Phillips.

BILHARZIA (Schistosomum Hæmatobium).—The position of the worms in the veins in the pelvis and abdomen prevents any radical treatment.

The symptoms due to the passage of the eggs through the mucosa can be alleviated. Rest is essential in severe cases, and over-exertion in all cases must be avoided. If the mucous membrane of the rectum be implicated, straining must be avoided, and the regular use of aperients is indicated. In hæmaturia, particularly if any cystitis is set up, boracic acid, 10 gr. three times a day, hexamethylenamine in the same doses, or alkaline diuretics, will be of value, such as:—

℞ Sodii Bicarbonatis	gr xv	Spiritus Chloroformi	℥ x
Tincturæ Hyoscyami	ʒ ss	Infusum Buchu	ad ʒ j

Every four or six hours.

The possibility of the formation of calculus must always be remembered, and cirrhotic changes in the kidneys may be a late result.

Schistosomum Japonicum causes cirrhotic changes in the liver, the mesenteric glands, and the walls of the intestine. These may lead to dysenteric symptoms, simple diarrhœa, or ascites. There is no specific treatment. The conditions must be treated on general principles. In the early stages, the urticaria which is common requires nothing but palliative treatment.

C. W. Daniels.

BILIARY FISTULA.—This is due to obstruction of the cystic or common duct, or to faulty technique in establishing drainage of the gall-bladder by cholecystostomy. If the cystic duct is obstructed, a mucoid discharge escapes; if the common duct is obstructed, bile in large quantities discharges.

The treatment of the fistula depends on its cause: if a stone is impacted in the cystic duct, it may be possible to extract it with suitable forceps through the fistula; failing this the abdomen should be opened, and the stone removed either through the gall-bladder or by incision of the cystic duct.

Many cases are due to impaction of a stone in the common duct; occasionally the stone may be induced to pass on into the duodenum by the injection of warm olive oil and by plugging the fistulous opening; if this fails, the abdomen must be opened, and choledochotomy or cholecystenterostomy performed; the former operation is of course preferable.

A persistent fistula, in the absence of an impacted stone, should be treated in the first instance by freeing the gall-bladder from the surrounding structures to which it is adherent, and establishing free drainage of bile by means of a rubber tube sewn into the gall-bladder. In these cases the fistula is commonly due to kinking of the ducts from malposition of the gall-bladder, or to stenosis of the ducts from inflammatory adhesions; hence cholecystectomy is to be avoided unless the patency of the common duct has been clearly established. If palliative measures and the establishment of free drainage fail, cholecystenterostomy may be performed; but from the nature of the cases this is often extremely difficult.

Fistulæ due to obstruction of the common duct by malignant growth are best left alone; cholecystenterostomy as a palliative proceeding in cases of malignant disease is an operation involving great risk, and if successful adds little to the patient's comfort.

T. Crisp English.

BIRTH PALSY.—The usual lesion is Erb-Duchenne paralysis due to overstretching of the fifth cervical nerve; other divisions may be involved in severe cases, even to the whole plexus. It occurs with about equal frequency in head and breech presentations. Occasionally the paralysis is of the lower-arm type; this occurs usually after breech presentations with the arms extended, occasionally

Fig. 3.—Special splint for birth paralysis and some cases of infantile paralysis of the upper limb.

Fig. 4.—Special splint applied to a case of birth paralysis.

after face presentations. It is not common to find the lesion diagnosed at birth. Often the child comes under observation owing to tenderness in the clavicular region; in other cases it is noticed that the extremity is immobile.

In the usual type due to injury of the fifth anterior primary division, the arm is held close to the side, and the forearm is pronated and extended. When the first dorsal root is implicated, the intrinsic muscles of the hand are paralyzed. But this is usually associated with injury to the eighth cervical, affecting the flexors of the fingers.

TREATMENT.—If seen early, the arm must be bandaged to the side with the paralyzed muscles relaxed and kept absolutely at rest; as soon as all tenderness has disappeared, massage and movements must be employed. Special care must be taken to avoid deformity due to contractures in the opposing muscles. In the Erb-Duchenne type, the splint devised by Fairbank should be employed. (See *Figs. 3 and 4.*) Under this treatment incomplete injuries are likely to improve, and the prognosis is favourable. Sixty per cent of the cases under my care have recovered completely without operative interference. If at the end of three months from birth the reaction of degeneration is present in the affected muscles the sooner operation is carried out the better. As a rule the faradic

reaction is present in the muscles of a child of two months, so that three months is a safe limit. If the reaction of degeneration is present when the child comes under observation, operation should be performed. The upper cords of the plexus are easily exposed by an incision in the posterior triangle of the neck. The anterior primary divisions of C5 and C6 must be exposed, together with their junction and division, and the origin of the suprascapular nerve. The scar will usually be found in C5 just at its junction with C6; in some cases the upper trunk will be found damaged. In other cases the fifth anterior primary division is found torn through. The damaged portion of the nerve must be removed and the ends united in the usual way. No difficulty will be experienced in most cases in bringing the ends together. If there be tension, the shoulder should be elevated and the head inclined to the affected side. If the ends cannot be brought into apposition, or the upper end cannot be found, nerve anastomosis should be carried out. If the lesion involve the lower divisions, it will be necessary in most cases to temporarily divide the clavicle.

After-treatment must be faithfully carried out; if this is done the prognosis is good.

Before operating it is essential to discover that the paralysis is due to a peripheral and not to a cerebral lesion. In the latter case the muscles, though paralyzed, react to the interrupted current, and spastic changes are often present in the lower limb of the affected side. In most of these cases the cause of the paralysis is intracranial hæmorrhage at birth, and should have been treated at the time by trephining; in other cases it may be due to tearing away of nerve roots and hæmorrhage into the spinal cord. In either case, if seen later, nerve anastomosis offers the best chance of improvement.

James Sherren.

BLACKWATER FEVER.—No specific treatment is known. Quinine is useless, and in some instances has caused the attack, while in other cases its administration has been followed by a relapse. The parasites of malaria, if present before, usually disappear during the first few hours. In the rare cases where they continue to be present during the attack, quinine is necessary, but it is highly exceptional for this to be the case, and even then quinine hydrochloride or hydrobromide must be given in very small doses, $\frac{1}{2}$ to 1 gr. slowly increased. The great dangers of the disease are—(1) *Suppression of urine*; (2) *Death from cardiac failure*, the result of the rapidly developed extreme anæmia; (3) *Hyperpyrexia*.

1. **Suppression of Urine** is the most common cause of death. It will rarely occur when treatment is commenced at the onset of the disease; when very early treatment is not employed the results are less satisfactory. The hæmoglobin dissolved in the blood acts as a powerful diuretic, and the albuminous materials form casts obstructing the renal tubules—hence the suppression. This rarely takes place where a constant flow of urine is maintained, so that a liberal supply of fluids is necessary from the onset of the disease. Treatment by the mouth is successful, provided that it is commenced at the onset of the disease. In such cases frequently there is no vomiting. If it be not commenced till vomiting has set in, it is not to be relied on, and must be supplemented by saline enemata and saline subcutaneous injections. Some authorities prefer to give nothing by the mouth, and supply the requisite fluid entirely by rectal injections. Frequent administration of water by the mouth (4 oz. or more every hour, or in more frequent smaller doses) will suffice, provided there be no vomiting. If, as commonly occurs, there be vomiting, hourly enemata of warm water (6 to 8 oz. if these amounts are retained) will produce the same free flush. These enemata are retained better if a little salt (1 teaspoonful to the pint) is added. Large subcutaneous injections of sterilized normal saline solution

(sodium chloride 0.6 per cent) are equally effective, but painful. The risk of the onset of suppression diminishes after the urine clears, but as at this time the diuretic effects of the hæmoglobin in the blood-serum are removed, the rate of excretion is much diminished. Persistent hiccough is sometimes noted, and is best treated by the application of blistering fluid to the side of the neck over the course of the pneumogastric nerve.

2. Death from Cardiac Failure becomes more probable as the anæmia advances, and is rare before the third day. Absolute rest in bed in the recumbent position is necessary. The patient must not be allowed to leave his bed or even to sit up for any purpose. When, as is often the case, there is much restlessness, small doses ($\frac{1}{10}$ or $\frac{1}{12}$ gr.) of morphia, given hypodermically, will relieve. Alcoholic stimulants in medicinal doses are required after the second day.

3. Hyperpyrexia may occur during the hæmoglobinuric period, or some days after the urine has cleared. It must be treated by cold applications, cool baths, etc. It is not malarial, and quinine and antipyretics are useless.

A large number of drugs have been employed, some of which are injurious. Alkaline diuretics and boracic acid appear to give good results, and Sternberg's method of treating yellow fever has in the hands of Hearsay invariably proved successful. (See YELLOW FEVER.)

Convalescence is rapid and usually complete. Iron, arsenic, etc., may be used in the late stages of convalescence. In the early stages they are useless. After leaving Africa, recurrences and relapses may occur for some months, and for longer periods in those in whom such attacks are induced by quinine. In cases where fever recurs after an attack of blackwater fever and it is proved by blood examination to be malaria, quinine hydrochloride should be given, $\frac{1}{2}$ gr. twice a day the first day, and every four hours the second day, 1 gr. every six hours the third day, and so on till the minimum dose that will be effective is reached, and then continued for a full three months in 2- to 3-gr. doses night and morning. Return to Africa or to any highly malarious country is not advisable in a person who has had blackwater fever. C. W. Daniels.

BOILS.—A boil is an infective gangrene involving a small area of the cutis, in most instances starting around a hair follicle or in a sebaceous gland; in this respect it is closely allied to acne. When the infective process is more extensive and involves the deeper layers, it becomes a carbuncle. These infective conditions are liable to arise in those who suffer from diabetes or albuminuria, and it is always necessary to examine carefully for these pathological conditions in any case of extensive infection with boils. Apart from these constitutional diseases, patients who suffer from boils usually show a very low resistance to the staphylococcus, a point to be specially considered in connection with the treatment.

TREATMENT.—*Local Treatment* consists chiefly in applying an antiseptic dressing after careful purification of the surrounding skin. In many cases the boil aborts or becomes blind; that is to say, the inflammatory process subsides without suppuration. The general method of covering a boil with a poultice or fomentation is to be condemned, since it tends to disseminate the infection and to cause a fresh crop to erupt.

When once a boil has made its appearance as a conical, red, tender swelling, an excellent form of treatment is to cut out and apply a small piece of Unna's plaster, rather larger than the boil, with a small opening in the middle which should be over the centre of the inflamed area. The boil must be carefully protected from pressure or irritation, either by a pad of gauze or lint, or by means of a celluloid shield.

Another method of treatment applicable to those boils which have come to a head is to snip off the projecting point and to apply pure carbolic with the end of a match to the centre of the area.

Gallois treats cases as follows: A solution is made up of iodine (1 dr.) and acetone ($2\frac{1}{2}$ dr.); a probe surrounded with cotton-wool is dipped into this iodacetone and applied to the boils, giving them the appearance of so many "beauty spots." A piece of absorbent material large enough to cover the whole region is soaked in boric acid glycerin (glycerin 6 oz., boric acid 5 dr.), and this is applied as a dressing over the whole area. The dressing is renewed once or twice a day, according to the amount of discharge. To succeed in this treatment, M. Gallois insists that antiseptic precautions should be observed.

In cases where there are considerable induration and pain, relief will be afforded by a free incision into the brawny mass.

General Treatment consists in free purgation and the administration of tonics—iron, arsenic, and quinine. The sulphide and the iodide of calcium have been used with much success. Yeast extract is another valuable remedy in recurring boils. Wonderful results are sometimes obtained from the administration of dilute sulphuric acid in large doses (e.g., 20 to 30 min., well diluted, every four hours).

Vaccine Treatment.—The condition of furunculosis, or the general development of boils, being due to a lowered resistance to a staphylococcal infection, Wright has treated patients by means of a staphylococcal "vaccine," the object being to increase the opsonic index and so the general resistance to this micro-organism. The results of this method fully justify its wide application. (See also BIER'S HYPERÆMIC TREATMENT.)

W. H. Clayton-Greene.

BONE, INFLAMMATIONS OF.—Inflammation of bone may be acute or chronic. The acute cases are almost invariably due to the invasion of the bone by pyogenic organisms, while the chronic ones are due generally to syphilis and tubercle; less commonly to the *Staphylococcus aureus* and *albus*. The typhoid bacillus is occasionally responsible for cases of chronic and subacute inflammation. The staphylococci are the principal causal agents in the production of acute inflammations; less frequently the *Streptococcus pyogenes*, and rarely the *Pneumococcus*.

Usually the disease starts at the growing end of the diaphysis of a long bone of a child or adolescent. The terms "acute infective periostitis" and "osteomyelitis" indicate the part of the bone principally involved. "Acute diaphysitis" reminds the surgeon of the site of the original infection. In infants, the epiphysis may be the seat of the process, and as in this case the joint is invariably infected, the condition is often known under the name of "acute arthritis of infants." The old name, "acute necrosis," indicates the almost invariable effect on the bone of the more virulent forms.

Lately, the view has been expressed by many surgical writers, particularly in France, that acute and subacute invasions of bone by attenuated cultures of pyogenic organisms may terminate in resolution, or may be responsible for an exudation which differs materially from pus. These views of the pathology of such conditions find expression in the terms "growth fever," and albuminous or serous periostitis or osteomyelitis.

Growth Fever usually occurs between the ages of seven and fifteen; it may be provoked by fatigue, slight injury, or cold. It affects the more actively growing extremities of the long bones, i.e., the lower end of the femur, the upper end of the tibia, the upper end of the humerus, and the lower ends of the radius and ulna.

The chief characteristics of the condition are areas of deep tenderness near a joint, and increased growth of the limb; there may be accompanying malaise and slight fever. The condition is an uncommon one, and its chief interest lies in the diagnosis, as it is frequently mistaken for early tuberculous disease of the neighbouring joint. A few days' rest in bed will usually clear the matter up, as the minor affection quickly subsides with rest, and it may be found later that there has been considerable growth of the affected limb. This may be the explanation of the inequality of the lower extremities which is so often found in adolescents, and which may be first noticed after a slight febrile attack.

The treatment consists in rest, with tonics and fresh air. Care must be taken that no weight or strain is placed on the bone so long as there is tenderness. Salicylate of soda will relieve the pain when the latter is marked.

The treatment of cases of acute microbic invasions of bone has to be considered under two heads: (1) The treatment of the acute condition; (2) The treatment of certain sequelæ and complications.

Acute Infective Periostitis and Osteomyelitis.—These cases belong to the class of surgical emergencies. Their treatment is by immediate operation. An incision should be made down to the bone, over the area of maximum tenderness, the periosteum incised, and the pus, if any, liberated. In almost all cases the medullary canal should be opened, either by a trephine or a gouge, and if pus be found, a spacious gutter should be cut in the bone, exposing the interior of the medullary canal, until a healthy area is reached.

The question of the necessity of exploring the medulla will always arise, and should be answered in the affirmative in all but a very few cases. The incision should be planned to avoid important structures, particularly nerves, but at the same time should be made as near to the point of maximum tenderness as is possible. The frequency with which the disease originates at the growing end of the diaphysis, almost invariably selecting the more fertile of the two extremities, is a useful guide to the surgeon in planning his incisions. Counter-openings should be made for drainage, and this must be free. For this reason tubes appear to be more useful than gauze or worsted. The use of powerful antiseptics in these cases is still a moot point among surgeons, some preferring to paint the infected area with 2 per cent solution of iodine in spirit, or with pure carbolic acid, while others, eschewing the use of antiseptics entirely, irrigate the wound with sterilized saline solution. The latter procedure certainly has the support of modern research, which has shown us that chemical substances inhibit phagocytosis, the most important part of that reactive process whereby the organism resists microbic invasion. In those cases where the pus is offensive, swabbing the infected area with peroxide of hydrogen appears to be of benefit. In many cases it is obvious, at the time of the operation, that a large portion of the diaphysis is dead, and in a few cases of bipolar diaphysitis, where the process has simultaneously involved both extremities of the shaft, the diaphysis has been found practically loose in an abscess cavity. It is rarely, however, wise to remove the dead bone at this stage, because it is practically impossible to foretell the exact limit of the necrosis, and therefore either too much or too little bone might be removed. This particularly applies to cases in which, at this stage of the disease, it would appear that a certain length of the shaft is dead throughout its whole length; yet the sequel of the case shows that the necrosis is limited to a thin cylinder of compact bone, and that the cancellous bone inside this cylinder, though infected, is still capable of recovery. At this stage, therefore, the surgeon's endeavour should be to provide adequate drainage, particularly of the medullary cavity. Convalescence is necessarily slow, with continuous suppuration, while the involucrum, or shell of new bone, is being formed and the

sequestrum is separating. With careful dressing to avoid contamination by other organisms, the suppuration can be reduced to a minimum, and the discharge from the sinuses is often practically clear. Such a case may run a painless and afebrile course.

The limb must be carefully splintered, lest fracture of the newly-formed shaft should occur. The patient should, however, be allowed out of doors, on a couch or spinal chair, as both sunlight and fresh air are important factors in maintaining the general health, and in thus aiding the processes by which the sequestrum is separated. It must be borne in mind that the separation of the sequestrum belongs to the vital process of repair, and is inhibited by sepsis and excessive suppuration. Surgical cleanliness is therefore imperative, to prevent the ingress of new microbes. The surgeon of to-day has, in addition, a useful weapon in the shape of inoculation of vaccines, which increase the patient's resistance to staphylococci. It is usually better to prepare the vaccine from a cultivation of the patient's own pus.

The few cases in which it does not appear necessary to drain the interior of the bone are those where a considerable subperiosteal abscess has formed with only slight constitutional disturbance. Such cases, however, require careful watching, and, if the temperature does not subside after simple incision and drainage of the abscess, a second operation must immediately be undertaken to explore and drain the interior of the bone.

Removal of the Sequestrum.—The selection of the best time to remove the dead bone requires careful consideration. It is usually better to wait until the sequestrum is loose, or its limits are so clearly defined as to enable the surgeon to remove the whole of it, and at the same time not to encroach unnecessarily on the surrounding bone. Time should be given also for the formation of an involucrum of new bone sufficiently strong to withstand the pull of the muscles and to sustain the weight of the limb. This shell of new bone appears to be moulded on the old and dead shaft. This fact constitutes an important reason for waiting before removing the sequestrum in the case of the femur and humerus, because neither of these has a companion bone to act as a splint and to maintain the shape of the limb while the new bone is consolidating.

Röntgen rays may occasionally prove of signal utility in locating the sequestrum and demonstrating its size and shape. In a recent case the newly-formed bone is more pervious to the rays than the sequestrum, and therefore the latter appears as a dark shadow surrounded by a lighter shadow representing the involucrum.

The incision in the operation of sequestrotomy must be an adequate one, and must be planned to avoid important nerves, e.g., the musculospiral above the elbow. It should bear a close relation to the existing sinuses, and these should be disinfected, as far as possible, with solution of iodine or with pure carbolic acid, at the commencement of the operation. The new bone must be chiselled or gouged away, and the sequestrum thoroughly exposed. The granulation-lined cavity, in which the dead bone has lain, is carefully scraped and cleaned, and its interior systematically searched for minute fragments of dead bone. In order to facilitate the thorough search for outlying pockets of the main cavity, some surgeons render the limb bloodless by raising it and applying an Esmarch's tourniquet above, but this measure is only rarely necessary. After the cavity has been carefully cleaned and the wound irrigated with sterile saline solution, the whole wound is packed with sterile gauze, and this must be repeated daily, the wound being allowed to granulate up from the bottom. The process is often a tedious one, and attempts have been made to shorten it by filling the cavity with such substances as bismuth paste (sterilized bismuth carbonate, 30 grams, white wax 5 grams, soft paraffin 5 grams, vaseline 60 grams—Emil Beck), or by sterilized iodoform wax (iodoform 60 parts, spermaceti 40 parts, and oil of

sesame 40 parts—Von Mosetig-Moorhof). The latter substance is heated and poured while still warm into the cavity, which has been previously dried carefully by a current of hot air. The success of these measures depends entirely upon the degree of asepsis of the cavity. As a rule, if all the sequestra have been removed and only healthy bone remains, the cavity granulates up with surprising rapidity without the use of any "filling"; whereas, whatever means be employed, failure is often the result if the cavity is markedly septic. It is therefore to the maintenance of asepsis that the surgeon must chiefly direct his attention.

Bier's method of treatment by passive congestion is often of distinct value in these cases, and the application of a Martin's rubber bandage to the limb above the wound area, for two hours daily, often expedites the separation of the sequestrum, and afterwards hastens the closing of the cavity.

The Question of Amputation will arise at two periods.

1. During the original acute attack. It is, however, questionable whether an amputation will save a patient who, at the onset of the attack, is poisoned to an extent sufficient to suggest the need of such a drastic measure. Such a patient is probably suffering from an acute septicæmia, and an operation of such severity merely depresses him still further, without very materially decreasing the toxæmia, which is due to a general infection of the circulating fluids and of important viscera. The case differs somewhat when there is, in addition to the bone disease, suppuration in the neighbouring joint. In this case it is possible that the majority of the toxins are being manufactured in the infected area, and are being absorbed into the general circulation through the medium of the synovial membrane, which possesses a special capacity for absorption. Amputation rids the patient of this absorbent area, and therefore early operation is often imperative in a case of infective osteomyelitis of marked virulence, in which there is also suppurative arthritis of the neighbouring joint. One exception to this general rule must be made in the case of acute arthritis of infants, in which form of the disease incision and drainage would probably show a lower mortality than would amputation; but in these cases, whatever be the treatment, the mortality is exceedingly high. During the last few years the writer has also seen several cases in which an osteomyelitis of the femur of a moderate degree of virulence was accompanied by pus in the knee-joint. As in all these cases, the evidences of constitutional toxæmia were not very marked, the joint was merely aspirated and the femur drained in the usual manner. Very satisfactory results were obtained, with a movable joint in each case. The question, therefore, of amputation must be decided on the degree of constitutional toxæmia present.

2. The second period at which the question of amputation has to be discussed is after the acute attack has subsided. It may then be evident that the patient, worn out with prolonged suppuration, is suffering from chronic toxæmia, as shown by hectic fever and evidences of lardaceous disease. Attempts have probably been made to remove the dead bone, but these efforts have been only partially successful, owing to the delayed separation of the sequestrum. This delay is due to the inhibition of the processes of repair by sepsis. Secondary hæmorrhage, or septic thrombosis, may have occurred, owing to the implication of the coats of an adjacent vein. Under such unhappy conditions, amputation is often the only treatment which will save life, but the question of its employment must be decided with reference to each particular case.

Since the more thorough appreciation of surgical cleanliness, such cases have become very much less common, and should become even more rare now that we have the means of increasing the patient's own powers of resistance to the infecting micro-organism.

The treatment of **Acute Infective Osteomyelitis of the Cranial Bones** when,

as occasionally happens, it gives rise to œdema of the scalp and to intracranial suppuration (the condition known as "Pott's puffy tumour"), must be conducted on the above lines. In this case, however, a disc of bone should be invariably removed, to secure drainage of the interior of the skull.

Chronic Osteomyelitis and Periostitis may be due occasionally to pyogenic organisms. The clinical forms under which this may occur are : (1) One form of abscess of bone ; (2) Quiet necrosis ; (3) Necrosis with suppuration ; (4) Albuminous or serous periostitis, due to subacute infection by an attenuated culture of *Staphylococcus aureus* or *albus*.

The chief interest in these cases lies usually in the question of diagnosis, as they are often mistaken, on the one hand for growths of bone, and on the other for tubercle or syphilis.

The treatment is incision, the removal of any sequestrum, and drainage. It is particularly in these chronic cases that the inoculation of a specific vaccine is of value, as is also Bier's treatment by passive congestion. Various plastic operations have been devised with the object of filling up the cavities in bones from which sequestra have been removed. Flaps of bone with periosteum, or periosteum and muscle have been utilized for this purpose. Should the cavity which is left after the removal of a sequestrum not show signs of closing in spite of careful and aseptic dressing, the most satisfactory procedure is to cut away the sides of the cavity so as to render it as shallow as possible, to allow the soft parts to grow into it. Occasionally a Thiersch's skin graft can be utilized to cover a central area over which the skin has not grown.

In certain long-standing and recurrent cases of chronic septic osteomyelitis, Charters Symonds has employed continuous drainage by means of metal drainage tubes, and has allowed the patient to walk about. This method of treatment appears to be well worthy of an extended trial in selected cases. *V. Warren Low.*

BONE, TUBERCULOUS DISEASE OF.—The general treatment for tubercle of bone, as for localized tubercle elsewhere, must be directed towards two objects, viz., preventing the spread of the disease locally and its dissemination generally, and increasing the patient's power of resistance to the disease. This latter property has been found to reside chiefly in the circulating fluids, in the shape of certain protective or bactericidal substances, of which the agglutinins, bacteriolysins, and opsonins are examples. It is therefore essential to increase the quantity of these substances present in the blood, and also to augment the circulation through the affected area, in order to flush the diseased tissues with a maximum quantity of lymph charged with protective substances.

It often happens that the diseased area is practically shut off from the action of the circulating fluids, owing to its being surrounded by inert material, granulation tissue, or pus, which has been deprived practically of all protective substances. The mechanical removal of this material is therefore an important and essential part of the treatment.

With these principles in view, the details of treatment vary somewhat with the bone affected.

In all cases the most important measure to prevent extension or dissemination of the disease is physiological rest. The diseased bone must be relieved of all strain, whether produced by the weight of the body or by muscular action. Disease of the vertebral column requires the supine position. Careful splinting, to include the joints above and below the affected bone, is required when a limb is the seat of the disease.

The next most important factor in preventing extension or dissemination of the tuberculous focus is freedom from contamination by pyogenic organisms.

This point has chiefly to be considered under the head of operative procedure, but it has also to be taken into account at all stages of the disease, as it is particularly important that a migratory tuberculous abscess should not become contaminated either by opening on the surface of the body, or, as occasionally happens, by coming in contact with a viscus, e.g., the kidney or bowel.

It has been abundantly shown, both clinically and experimentally, that tuberculous infections of bones and joints are more prone to become disseminated in the blood-stream and to extend more rapidly locally, when there is contamination with pyogenic organisms. This fact was responsible probably for a prejudice that existed among experienced practitioners twenty years ago against opening tuberculous joints. This measure was stated to increase the risks of generalized tubercle. Increased resistance of the patient's tissues and circulating fluid to the tuberculous invasion can be obtained by (1) Open-air treatment; (2) Inoculation of small doses of Koch's tuberculin.

The value of fresh air and sunshine in the treatment of scrofulous glands and joints was realized at an earlier period than was the importance of the same agencies in the treatment of pulmonary tubercle; and yet, at the present time, liberal provision is made for the open-air treatment of pulmonary tubercle, but very little has been done to secure equal advantages for patients suffering from what is known as surgical tuberculosis. Properly organized open-air treatment is, however, of the greatest value in these cases of osseous tuberculosis, and should be combined with absolute rest of the affected bone. It must always be borne in mind that these patients should not be treated together with sufferers from pulmonary disease, because the former are liable to pulmonary infection in a greater degree than are healthy persons.

The question of feeding is an important one, the essentials being a plentiful supply of easily assimilable food, and the absence of any fresh infecting material. For this reason, the milk supply should be above suspicion, and the dietary should contain sufficiency of animal fats in an appetizing and easily digestible form. Cod-liver oil is invaluable in these cases, and is usually prescribed with iron or maltine, the latter combination being the more palatable.

The treatment of localized tubercle by the inoculation of small doses of Koch's new tuberculin has now been firmly established. The doses are smaller than those at first employed; $\frac{1}{100000}$ to $\frac{1}{200000}$ mgm is the amount usually given. Tubercle of bone, being a good example of localized tubercle, is well suited to inoculation treatment, and by means of it excellent results have been obtained.

"Open-air treatment" and inoculation are alike directed to increasing the amount of protective substances in the patient's blood and lymph. In order to bring the maximum quantity of these protective substances into contact with the diseased tissues, it is essential to increase the circulation through the infected area. This object is achieved by various forms of mild local stimulation, such as application of Scott's dressing, or painting with iodine. Fomentations have the advantage of being anodyne, and at the same time they are a cleanly means of stimulating the local circulation. If pain is a prominent symptom, the parts may first be painted with glycerin of belladonna. If a sinus be present, or the skin be infected, the material employed in fomentation should be impregnated with boracic acid. Of recent years, Bier's method of treatment by producing local congestion has been extensively used in this country, and its employment has been attended with a considerable measure of success. This method is applicable only to cases of local tuberculosis in limbs, and consists in constricting the limb by means of a light elastic bandage—e.g., a Martin's bandage. The constricting force should be sufficient to block the venous return without interfering with the arterial supply. The constriction should be applied for periods

varying from two to three hours or more, and can be repeated daily. (See BIER'S HYPERÆMIC TREATMENT.)

With the earlier diagnosis of tuberculous osteitis, and with the therapeutic measures outlined above, which endeavour to imitate the natural process of cure of the disease, the necessity for operation ought to become increasingly less. There will still, however, remain a number of cases in which the mechanical removal of a sequestrum, or the liberation of pus, will be necessary in order to permit access of the circulating blood and lymph to the diseased tissues. Such operations must be performed under the most stringent asepsis, and this must be maintained during the after-treatment. For this reason it is important to avoid, as far as possible, the use of drainage—always a prolific source of wound infection. The sequestrum should be removed, or the pus liberated, the cavity carefully wiped out with sterile gauze, and the wound closed. It is possible, in the case of an abscess, that this operation may have to be repeated; but the result of two or even three such operations is preferable to the older method of incision and drainage. No useful purpose is served by the use of such chemicals as iodoform, sulphur, zinc chloride, or pure carbolic acid in the abscess or bone cavity. Such substances inhibit the natural processes of cure, while the patient's own lymph, with which the parts are flushed after the removal of the pus, is the most suitable bactericidal agent for his own case. In order to avoid infection of the surface wound by the abscess cavity, the deeper structures should first be sewn up with catgut stitches. Should the circumstances of the case render an aseptic operation difficult of accomplishment, it would be better to aspirate the contents of the abscess cavity rather than to risk the formation of a sinus. Under suitable conditions of rest and open-air treatment many such tuberculous abscesses have been cured by simple aspiration. This has been amply illustrated at the Maritime Hospital, Berck-sur-Mer, and at Treloar's Home at Alton, where excellent results have been obtained after aspiration of abscesses in connection with tuberculous bone disease. Drs. Gauvain and Calvé, writing in connection with these hospitals, also advocate the use of certain modifying liquids, e.g., iodoform dissolved in ether 5 to 10 per cent, or camphorated thymol (2 parts of camphor and 1 part thymol dissolved in equal parts of sulphuric ether); 2 to 5 c.c. of either of these fluids are carefully injected into the abscess cavity from which the pus has been aspirated, and the needle is allowed to remain in position while the vapour resulting from the volatilization of the ether escapes.

The present writer, in preference to the use of these chemicals, washes out such abscess cavities with sterile saline solution by means of a Record syringe with a two-way tap.

The formation of a sinus is always a serious complication in a case of tuberculous osteitis. It invariably means a double infection, and we have to deal with a pyogenic as well as a tuberculous invasion. Operations in such cases are not aseptic, and there is always a risk of an extension locally, or even of a general dissemination, following any operative interference. General treatment, including rest and exposure to fresh air and sunshine, must be persevered in; while local measures, such as boric acid fomentations and Bier's "compression," must be directed to increasing the lymph circulation through the infected area. Inoculation is necessary to raise the power of resistance both to tubercle and to the special pyogenic organism which has been found to be most prevalent in the sinus. This is generally a staphylococcus. The presence of a sequestrum, as shown by the probe or by the x rays, or as suggested by the persistence of the sinus in spite of treatment, will require operation.

In such a case, the operation should take the form of a deliberate search for a necrosed area of bone, and should not consist of the vague scraping procedure so often employed on these occasions. It is unfortunately impracticable, as a

rule, to close the wound entirely, and therefore drainage is necessary, with the usual result of another sinus. This second sinus may, however, close after prolonged treatment, but until it does so its presence is always a source of danger to the patient. Indeed, it cannot be too strongly emphasized that the most important point in the treatment of tuberculous osteitis is the prevention of sinus-formation.

A case of uncomplicated tuberculous osteitis is seldom fatal ; nor is amputation often necessary when the disease affects a limb. Such cases are invariably due to secondary infection with other organisms, and call for the principles of treatment set forth in the article on pyogenic diseases of bone. (See BONE, INFLAMMATIONS OF.)

The treatment of tuberculous osteitis may be summarized by the following examples.

Should the disease affect the trochanter of the femur, with a cold abscess in the thigh :—

1. Rest on a couch or bed with a Liston's or Thomas's hip-splint.
2. Exposure to open air and sunshine.
3. A diet including plenty of milk and of animal fats.
4. Inoculation with small doses of Koch's new tuberculin.
5. The abscess should be carefully aspirated, and its cavity washed out with sterile saline solution by means of an aspirating syringe with a two-way tap. Should this measure fail, or an *x* ray photograph demonstrate the presence of a sequestrum, the abscess must be opened under the strictest asepsis, the sequestrum removed, and the cavity closed by buried catgut stitches, the skin being sewn up separately.

A case of tuberculous osteitis of one of the phalanges in a child would require, as before, open-air treatment and splinting, with fomentation. Bier's compression is particularly useful in these cases. Therapeutic inoculation should also be employed, when the circumstances of the case allow it. If there be evidence of pus-formation, or if the *x* rays show the presence of a sequestrum, an incision must be made, the pus liberated or the sequestrum removed, and the skin carefully sewn up again. It is rarely necessary to remove the finger, and the majority of cases recover, though occasionally the resulting finger is shortened and stiff, and the patient prefers to have it removed. It is better, in spite of this possibility, to defer amputation in such a case until the disease is cured, as it is impossible to foretell what the result will be in any individual case, and the most unpromising ones have healed, leaving a useful limb.

(See also JOINTS, TUBERCULOUS DISEASE OF THE ; PHTHISIS ; and SPECIFIC THERAPY.)

V. Warren Low.

BONE, TUMOURS OF.—Osteomata may be compact or cancellous. The former occur in connection with the cranial bones, and are sessile tumours composed of dense compact tissue of the consistence of ivory. Their removal is rarely within the range of practical surgery. Should, however, the position and circumstances of such a tumour demand an operation, the surgeon must not forget that the bone forming the tumour is extremely hard, so that, unless the incision for its removal can be carried entirely outside the tumour, and in healthy bone, it is necessary to make use of mechanical saws and drills of fine temper, and worked by an easily controlled motor.

Cancellous or spongy osteomata are usually pedunculated tumours, and grow in the vicinity of the epiphyseal lines of the long bones. They are often symmetrical. Their removal, when necessary, is an easy matter ; the soft cancellous bone at the neck of the tumour is easily cut with a chisel or bone

forceps, and the tumour shelled out from the adjacent soft parts. Strict asepsis is necessary, as these tumours grow in the close vicinity of joints. By their removal, also, the cancellous tissue of the bone to which they are attached is opened.

Subungual exostosis is an irregular outgrowth of bone which occasionally occurs on the ungual phalanx of the great toe, pushing up and deforming the nail. It is probably inflammatory in its nature, and arises from the pressure of unsuitable boots. Its removal is effected with a sharp spoon, after the nail has been removed. Recurrence is probable unless properly shaped boots are worn.

Chondromata occur in connection with bone, and may occasionally require removal. They are often multiple and symmetrical, and occur most frequently in connection with the phalanges and metatarsal or metacarpal bones. They are definitely encapsuled, and can, as a rule, be easily shelled out of their capsule. In the majority of cases this simple measure is successful.

Myelomata.—Within the last few years, pathologists have differentiated between myeloid sarcomata of bone and pure myelomata, and have removed the latter from the category of malignant tumours. These tumours consist almost entirely of large multinuclear cells, and grow in the medullary cavity of the shafts of long bones, immediately adjacent to the epiphyseal cartilage. The diagnosis between a myeloma and a myeloid sarcoma can be made only by the careful examination of properly prepared microscopic sections, and this should be carried out by an expert pathologist in conjunction with the surgeon. The portion of growth required by the pathologist must be removed by a formal operation, and the incision carefully closed.

When the diagnosis has been firmly established, a myeloma may be dealt with by enucleation, or by resection of part of the bone. The former operation is more suitable when the tumour is completely contained within a cavity in the bone, and can be easily separated from the wall of the cavity. Enucleation is also a more suitable operation where resection is impracticable, as in the lower end of the femur and upper end of the tibia. In the case of the radius, ulna, clavicle, and fibula, resection of part of the bone should be performed. It cannot be too strongly insisted upon that in the case of the humerus and femur, where the diagnosis is in any doubt, it would be safer to amputate at once.

Endotheliomata may occasionally implicate, by their extension, the cranial bones, and also the mandible. In connection with these tumours, it must be remembered that they appear to possess only a local malignancy, and this not always of a particularly marked type. Consequently, operations, such as would scarcely be justifiable were the tumour a sarcoma, may be undertaken for their removal, as even in cases where apparently portions of the tumour have been left behind recurrence has been delayed, in some instances indefinitely, and the patient's condition has therefore been considerably relieved.

Cysts of bone, with the exception of the rare parasitic cysts, are of uncertain pathology. Some appear to be new growths which have undergone degenerative changes, while others are undoubtedly of inflammatory origin and represent an osteomyelitis due to organisms of a low degree of virulence. The treatment of these cysts of bone varies with the view held as to their nature. Surgeons who are impressed with the frequency with which bone cysts are due to a chronic inflammatory condition, are content to empty the cyst, scrape out the lining membrane, and either fill the cavity with some stopping, as bismuth paste or iodoform wax, or, when the enveloping bone is thin and brittle, to place an ivory rod in the medulla to act as a splint or framework while the new shaft is being formed. Others who believe these cysts to represent new growths, whether innocent or of a low malignancy, prefer to excise the portion of bone in which

the cyst is situated, and either to replace it by a rod of ivory (in one case an ebony rod was used with great success), or to transplant a piece of living bone, preferably from the patient, e.g., a portion of the fibula, a splinter from the tibia, or a rib. Excellent results have been recorded by both these methods. The writer prefers an ivory rod in the case of the upper extremity, or when the excision has been sub-periosteal and only a small portion, 3 to 4 inches, of the bone has been removed. For the lower extremity, and where some 7 or 8 inches of bone have been removed, the fibula from the same patient is preferable.

Sarcomata of bone may be central or periosteal. Both varieties occur more frequently at the extremities of the long bones than at the centre of the shafts. The bones of the lower extremities are more frequently affected than those of the upper.

The treatment of all cases of sarcoma of the bones of the extremities should be amputation of the limb well above the tumour. Wherever possible, the amputation should be by skin flaps with circular division of muscles. In nearly all cases, the affected bone should be removed, so that the site of the amputation is usually at the joint above the tumour. In the case of a round-celled sarcoma of the tibia, it should be through the lower third of the femur.

A few exceptions to the general rule that the affected bone should be removed may be quoted. In the case of a sarcoma of the lower end of the tibia or fibula, in which an adult tissue, as cartilage or fibrous tissue, predominates over the cellular elements, amputation may be performed through the upper third of the leg.

In the case of a round-celled sarcoma of the femur, unless the diagnosis has been made within a few weeks of its earliest appearance, the prognosis is so extremely bad that it has been a question whether the patient should be subjected to such a severe operation as an amputation at the hip joint, since even this offers only a small prospect of ultimate cure. The palliative measure of a subtrochanteric amputation has therefore been suggested, since it presents fewer immediate risks, and will at the same time save the patient the miseries that attend a fungating and septic growth. But on the other hand, an amputation at the hip-joint does slightly improve the prognosis in these cases, and the immediate dangers of the operation may be lessened by careful provision against shock and against loss of blood by carefully tying the main vessels at the commencement of the operation. The writer is therefore of opinion that the major operation should be performed in all cases of sarcoma of the femur. Only skin flaps should be employed, and the muscles should be cut as short as is practicable.

In the case of a sarcoma of the humerus, Paul Berger's amputation of the upper extremity appears to give a lower mortality than amputation at the shoulder-joint. As sarcoma usually affects the head, or the upper third, of this bone, Berger's operation is in every way the more suitable one. Unfortunately, the prognosis, in respect of recurrence, is extremely bad in these cases.

Sarcomata, either central or subperiosteal, occur in the clavicle, scapula, jaw-bones, and occasionally in the ribs, and may be amenable to surgical treatment, if discovered early enough to justify excision of the affected bone. Sarcomata of the cranial bones, vertebræ, and pelvis are rarely fit cases for operation.

The writer's experience of the use of Coley's fluid for inoperable cases of bone sarcoma has been uniformly disappointing, and there appears to be little justification for its use in such cases. The burying in the tumour for twenty-four hours of a large dose of radium or radium emanation appears to offer some slight hope of success. At present, however, the reported cases are so few in number, and the evidence of the nature of the growth in some of the successful cases so equivocal, that this method of treatment can only be regarded as being in its experimental stage.

V. Warren Low.

BORBORYGMI.—Excessive rumbling in the bowels is usually a sign of a neurasthenic state. It may therefore be necessary in extreme cases to put the patient through a rest cure (see NEURASTHENIA). In milder cases the diet should be regulated as for FLATULENCE (*q.v.*), sweets, pastry, and tea especially being forbidden, the bowels regulated, and a firm abdominal binder ordered.

Robert Hutchison.

BRADYCARDIA.—This term is applied to an undue slowing of the pulse-rate. Patients who manifest an infrequent pulse may be divided into four groups.

1. There is slowing of the whole heart. This is not necessarily an indication of disease. A pulse-rate of fifty is not infrequently found in persons of sound constitution, in whom it is an idiosyncrasy and consistent with excellent health.

A true bradycardia in which all the chambers of the heart are involved is common during the period of convalescence, especially in adolescents, and is of no significance.

Intracranial pressure, and toxins such as tobacco, tea, influenza, uræmia, and diphtheria, by their influence on the sino-auricular node, may also slow the heart.

2. Recurring extra-systoles, or premature and ineffective beats; they may be so feeble that they are not represented by an appreciable pulse-wave at the wrist.

3. Cases of auricular fibrillation or auricular flutter under the influence of digitalis, strophanthus, or squills. In patients suffering from auricular fibrillation, the members of the digitalis group tend to induce the coupled beats so characteristic of their action on patients with fibrillating auricles; the second systole of each couple fails to send a perceptible pulse to the wrist, the pulse-rate then being half of that of the heart. This form of arrhythmia may be mistaken for recurring extra-systoles. In such patients the bradycardia may be of a marked grade.

In a few instances, administration of the digitalis group to patients suffering from auricular fibrillation produces complete block, and the ventricles then beat independently of any stimulus reaching them from the auricles.

4. Patients in whom there is an interference with the conducting powers of the junctional tissues, eventuating in complete or partial heart-block. In heart-block the auricles beat normally; and when bradycardia is present it results from the blocking of some or all of the stimuli originating in the auricles as they attempt to cross the neuromuscular connection termed the auriculo-ventricular bundle, or Gaskell's bridge. The block may be incomplete, only a fraction of the stimuli being blocked, or it may be complete, in which case no stimuli will reach the ventricles from above. The ventricles then contract steadily—about twenty-eight to thirty-two beats per minute.

Bradycardia may be paroxysmal or persistent.

Where bradycardia is associated with periods of stoppage of the ventricles, the patient suffers from recurring attacks of loss of consciousness and convulsive twitchings. This complex is known as the Stokes-Adams syndrome. The periods of ventricular stoppage are characterized by varying degrees of symptoms, the severity depending on the duration of the stoppage. There may be nothing more than a transient mizziness, but complete syncope is not uncommon; and if the ventricular stoppage is prolonged beyond fifteen to twenty seconds, epileptiform convulsions appear. The severer form of attack may prove fatal.

TREATMENT.—The treatment of bradycardia depends on the recognition, in each instance, of the essential cause of the tardiness of the pulse.

Where the action of the whole heart is involved, as in those healthy individuals

who habitually present a slow pulse, or in the bradycardia of convalescence, no specific treatment is required, and the less the heart is tinkered with the better.

When the bradycardia is merely an evidence of excessive indulgence in alcohol, tea, or tobacco, the line of treatment is obvious; this bradycardia is rarely such as to endanger life, and with the removal of the cause the pulse-rate will gradually increase. If the bradycardia is extreme and persistent, massage and baths prove helpful.

The same line of treatment can be carried out in the toxic bradycardias sometimes met with in diphtheria and influenza. Strychnine is useful as a general tonic in such cases, though it is open to question how far it has any direct action on the heart.

Where the bradycardia is a manifestation of chronic or acute uræmia, the treatment must be eliminative (see URÆMIA).

The treatment of many of the patients classed in Group 2 is discussed under HEART, IRREGULARITY OF.

The bradycardia found in patients suffering from fibrillation of the auricles under the influence of digitalis and its allies may be very marked, a pulse-rate of forty and fifty being common. If the whole heart is correspondingly retarded, the digitalis must be stopped.

If the slow pulse is due to coupling of the heart-beats—the second beat of each couple proving ineffectual—the dose should be diminished until that dose is arrived at which is sufficient to steady the heart without unduly retarding it.

When the arteries are definitely sclerotic, some preparation of iodine should be administered, either the iodide of potassium or of sodium, in doses of 5 to 10 gr., or the tincture of iodine in 2- to 4-drop doses, well diluted with water.

R Potassii Iodidi	gr v	Tincturæ Nucis Vomiceæ	℥ xii
Liquoris Potassii Arsenitis	℥ iij	Aquam Menthæ Piperitæ	ad 3 ss

A tablespoonful thrice daily after food.

Most gouty patients benefit from a mixture containing colchicum and the alkalies.

It is well to reiterate that the majority of patients suffering from a slow pulse are better without treatment directed to the heart.

John Hay.

BRAIN, COMPRESSION OF.—In all cases of head injury of any severity, constant watchfulness must be maintained for the onset of signs of compression, for it is the early recognition of this condition, followed by the early removal of the compressing agent, that makes a favourable result possible.

The causes of compression of the brain after injury may be classified as follows :
(1) Depressed fracture; (2) Foreign bodies; (3) Intracranial hæmorrhage—
(a) Extradural, (b) Intradural; (4) Inflammatory effusions—(a) Meningitis,
(b) Abscess.

In the treatment of compression the obvious indication is to relieve the pressure by operation, and the methods employed will depend upon which of the above-mentioned causes is at work. (See SKULL, FRACTURES OF; HÆMORRHAGE, INTRACRANIAL.) The general treatment to be adopted may, however, be touched upon here. The patient is kept quiet in a darkened room, and an ice-bag may be applied to the head. The bowels are opened by the administration of a drop of croton oil in a little mucilage placed on the back of the tongue, followed by enemata. The urine is drawn off twice a day by catheterization. The patient is fed upon liquids by means of a nasal tube passed into the stomach. Stimulants must not be administered. There is a danger lest the patient should

suffocate through the rolling back of the tongue. This may be avoided, as a rule, by placing the patient on his side; should it occur, the tongue is pulled forwards with forceps.

Death occurs from respiratory failure, the heart continuing to beat for some time after the breathing has stopped. Artificial respiration is therefore called for at times to keep the patient alive while an operation is being performed for the relief of the pressure, the breathing, when this has been done, continuing spontaneously.

S. Maynard Smith.

BRAIN, CONCUSSION OF.—It is usual for the purposes of description to divide concussion into three stages: (1) *Collapse*; (2) *Reaction*; (3) *Convalescence*; but it must be recognized that the severity of the condition may vary greatly. Thus there may be merely a momentary loss of consciousness, the patient feeling giddy and confused. In cases of severe injury, on the other hand, death may ensue in a few minutes. In the majority of cases, however, which come under the care of the surgeon, the three stages mentioned are sufficiently well marked.

Stage of Collapse.—Whilst employing measures to restore the patient from his condition of collapse, it is of the utmost importance to avoid over-stimulation. It is impossible to say at this stage whether there be any laceration of the brain tissue or rupture of intracranial vessels. Undue stimulation will result in the starting of hæmorrhage from these ruptured vessels, or, by causing hyperæmia of the brain, will predispose to the occurrence of inflammatory affections or of spreading œdema. The patient should be put to bed immediately between warm blankets. Hot bottles are placed around his lower extremities and trunk, care being taken not to cause burns. If the collapse be great, a rectal injection of a pint of warm saline solution should be given. In rare cases it may be necessary to resort to the administration of brandy either per rectum or hypodermically, but the dangers of stimulation must be carefully borne in mind. If the unconsciousness be long maintained, nutrient enemata will be needed, or fluid nourishment may be given by means of a nasal tube.

Stage of Reaction.—The onset of reaction is often marked by vomiting; the pulse, at the same time, improves, the respirations become deeper, and consciousness returns. When this occurs a purge (calomel gr. 5) should be administered, followed if necessary by an enema. The diet should for a few days consist of "slops"; stimulants of all kinds must be avoided; and the utmost care should be taken to avoid all disturbing influences. Thus, the room should be darkened, the blinds being drawn and the lights shaded. The attendants should be warned to avoid noise in moving about the room, in attending to the fire, and in opening and closing the door. Should the reaction be considerable—as indicated by a raised temperature, continued mental disturbance, and severe headache—the head should be shaved and Leiter's tubes applied, whilst free purgation should be persisted in.

Convalescence.—Sufficiently prolonged rest from work and the avoidance of worry and mental excitement are the chief indications. It must be remembered that what may seem, at the time, to be a comparatively slight injury, may permanently unfit the patient for any responsible employment.

S. Maynard Smith.

BRAIN, LACERATION OF.—More or less laceration of the brain and its membranes is a frequent accompaniment of head injuries. If there be a compound fracture of the skull and the dura mater be torn, the lacerated area is in direct communication with the exterior, and the grave dangers of septic inflammation are added to those directly dependent upon the laceration. It may be

said that unless there be a depressed fracture of the skull or unless the violence be localized to a small area, the laceration is most marked at a point diametrically opposite to the point struck (*contre-coup* laceration). Thus it is not unusual to find convulsions and paralyses on the *right* side of the body when it is the *right* side of the head which has been struck, since as a result of the blow there has been a *contre-coup* laceration of the *left* motor area.

TREATMENT.—It is obvious that in all cases of contusion or laceration of the brain the primary symptoms will be those of CONCUSSION (q.v.). There are, however, several special symptoms which may arise in the course of the case and which call for special treatment. These are as follows :—

1. If there be a wound, the utmost care is taken in its disinfection, as described under the heading of SCALP WOUNDS. Depressed fragments of bone and foreign bodies are removed, prolapsed brain tissue is cut away, and if possible the torn dura is brought together with catgut sutures, a small drainage tube being left in.

2. If signs of compression, preceded or accompanied by early convulsions or paralyses, ensue, the cause is likely to be hæmorrhage into or upon the surface of the brain. The treatment is given under HÆMORRHAGE, INTRACRANIAL.

3. The peculiar train of symptoms known as “cerebral irritation,” coming on early after an injury, is due to a laceration of the frontal lobe. For treatment, see CEREBRAL IRRITATION.

4. Convulsions occurring at a later period—usually from the third to the fifth day—indicate inflammatory processes or a spreading œdema originating at and extending from the lacerated area. If the patient be young and the pulse full and hard, venesection to the amount of 10 or 12 oz. may be performed, and full doses of bromides given. If, in spite of this, the convulsions become more general, and the unconsciousness becomes more profound, the lacerated area should be exposed, the dura opened, and the clots removed. If the brain appears swollen and œdematous, a free incision into its substance holds out the best hope of success. In cases where there is no evidence as to the site of laceration, a subtemporal decompressive operation should be done.

S. Maynard Smith.

BREAST, INFLAMMATION OF.—(See MAMMARY ABSCESS ; MASTITIS.)

BREAST, NEURALGIA OF.—Pain may, of course, form one of the symptoms of any affection of the breast, but in speaking of mammary neuralgia one refers to those cases in which pain is the outstanding feature of the case, the local changes being slight or absent. This condition is very commonly met with amongst female patients.

The causes are diverse, and usually unobtrusive ; they may be divided into : (1) Local causes ; (2) Pelvic affections ; (3) Impaired general health. Local and general causes are often combined, and inseparably connected with both is the dread of cancer.

TREATMENT.—Before commencing treatment, it is essential to get a clear idea of the cause of the pain. Cure can rarely be brought about by merely covering up the breast with plasters or by the application of anodynes.

A very careful search must first be made for slight local lesions, and especially for small patches of localized mastitis. The condition of the pelvic organs must be inquired into, and treatment in this direction be instituted if necessary.

As has already been stated, it will be found that the fear of cancer is at the root of the trouble in the greater number of cases, and reassurance on this point will go far to cure the neuralgia. In fact, many of these patients come to us, not because the pain is a serious trouble, but in order to find out whether they have cancer. When we can honestly reassure them, as is often the case, the

pains will usually vanish. If we are confident that there is no local disease, it is well to be emphatic, for any doubt or hesitation on our part will lead to infinitely greater doubt in the patient's mind, and to exaggeration of the pain and worry.

Any local changes in the breasts will demand local treatment, but on the other hand it may be pointed out that, in the absence of local changes, it will often be unwise to order local applications, for these will tend to keep the patient's attention to the region, and usually fail to give relief. Where there is mastitis, mercurial ointment and the internal administration of sodium iodide should be used. The local application of x rays (half Sabouraud dose repeated three times at fourteen-day intervals) is often efficacious in mastitis cases, and should be given a trial. Should this treatment fail in patients over thirty, it will be wisest to excise the affected area freely. Small fibro-adenomata and cysts should be at once removed, and this step will almost always relieve the neuralgia.

When the general health is at fault, and is responsible for the neuralgia, the indications for treatment are clear. The most useful drugs are iron, quinine, and purgatives. Anæmia and insomnia must be promptly treated. In the neurasthenic cases, rest, general massage, and high feeding, or a change of surroundings, are advisable; the most effective form of local treatment in these cases is galvanism.

T. Crisp English.

BREAST TUMOURS.

1. Fibro-adenomata.—Very small tumours, causing no trouble, may be left alone unless the patient desires their removal. Otherwise removal should always be recommended, for the following reasons: (1) These tumours are almost always a source of worry and anxiety to the patient; (2) If she marries, they usually grow rapidly and give trouble during pregnancy and lactation; (3) In a small number of cases they ultimately assume a malignant character; (4) The diagnosis can never be absolutely certain, and tumours supposed to be fibro-adenomata occasionally prove to be early sarcomata or carcinomata, even in young subjects.

No external application of any kind has the slightest influence on the growth of a fibro-adenoma; liniments, iodine, x rays, and other "absorbent" remedies do nothing but harm.

The operation, although apparently a simple one, requires careful attention to detail. A full anæsthetic should be given; some recommend the use of a local anæsthetic, but this frequently leads to failure or to a hasty operation, for few women will bear an operation on the breast without a general anæsthetic. The *incision* should be a small one, and should be situated as low in the breast and as near its periphery as possible; an inconspicuous scar will thus be left; in some cases a little flap with its convexity downwards may be used in order to get the main part of the scar lower. Many recommend that the capsule of the tumour should be incised and the growth "shelled out." Personally, I feel that it is better practice to remove the capsule with the tumour, for cases are met with in which the tumours have recurred locally after being "shelled out;" in these cases a small lobule of the tumour has been left behind. Further, it occasionally happens that on microscopical examination the growth is unexpectedly found to be malignant; the fact that the tumour has been excised thoroughly will then be an advantage in any case; the complete operation should be strongly advised at once, but it may happen that the patient refuses a second operation, or insists upon waiting for a recurrence. After removal of the tumour, all bleeding points are carefully secured, and the cavity is closed by passing silk-worm-gut sutures deeply, and by means of buried catgut sutures;

a drain of a few strands of silkworm gut is employed for forty-eight hours. Unless the cavity be closed carefully, a hæmatoma usually forms, and will probably interfere with the union of the wound.

2. Cysts.—Cysts occurring in the breast may be grouped under the following headings: (a) Simple serous cysts; (b) Multiple cystic disease, including involution cysts; (c) Cysts connected with tumours; (d) Galactoceles; (e) Hydatids.

a. Simple Serous Cysts may occur in the breast apart from the presence of a tumour or intracystic growth.

TREATMENT.—These cysts may sometimes be cured by withdrawal of the fluid and the injection of two or three drops of pure carbolic acid; the acid excites inflammation and the cyst refills with fluid, which becomes absorbed in a few days, leaving the cyst obliterated. This method is *not* to be recommended; the result is uncertain, and moreover many of these cysts, which appear simple, are connected with tumour formation, which can be recognized only by incision; for instance, there may be a large cyst and a small, early carcinomatous growth. Tapping and injection should be employed only when the patient absolutely refuses the radical operation.

The best treatment is excision; the resulting cavity in the breast tissue must be obliterated as far as possible by passing sutures of silkworm gut deeply, otherwise a troublesome hæmatoma is liable to develop; a small drainage tube should be inserted and left in for twenty-four hours.

In operating upon these cases it is well to remember that other smaller cysts may be found, that the condition, in fact, is really multiple cystic disease; or cystic growth may be present. It is advisable, therefore, to obtain the patient's consent to remove as much of the breast tissue as may seem advisable.

b. Multiple Cystic Disease is usually the result of chronic lobular mastitis, and the treatment is based on the same principles as in chronic mastitis. Each case must be considered separately; in some the cysts may be dealt with one by one as they arise, by injection and tapping, or preferably by excision; in others, excision of a portion of the breast is indicated; in many, it is wiser to remove the whole breast.

c. Cysts connected with Tumour Formation (intracystic growths). If intracystic papillary growths are present, the case should be regarded with grave suspicion, since many of these cases are malignant in type. Free excision should be performed in the first instance, to be followed by a radical operation if the pathological report indicates malignancy. If the cyst is connected with a fibro-adenoma or a malignant tumour, the treatment is that of the tumour.

d. Galactoceles are cysts containing altered milk, which originate in lactation and are due to partial obstruction of one of the larger ducts.

TREATMENT.—Nothing as a rule should be done until lactation has ceased. The cyst should then be excised, and the cavity obliterated as far as possible by deep suturing; drainage for forty-eight hours should be employed.

Other methods, such as tapping and injection, free incision and stuffing with gauze, etc., are unsatisfactory, and should not be employed. A suppurating galactocoele is treated as an ordinary mammary abscess.

e. Hydatid Cysts are rare, and should be freely excised.

3. Malignant Tumours.—The only treatment for malignant disease of the breast is early and thorough operation, provided that there is a reasonable prospect of removal of the disease. Under certain conditions, palliative treatment only is possible. However small and early the growth, operation must not be delayed, for with each week of delay the prospect of cure diminishes. One would also point out emphatically that however small the growth, the extent

and thoroughness of the operation should never be diminished, for it is in these early cases that the prospects of cure are especially good.

RADICAL OPERATIONS.—The term "radical operation" is used for those operations in which an attempt is made to procure a radical cure by the removal of the whole of the disease; in former days this expression would scarcely have been admissible, in view of the large number of cases in which recurrence took place. The experience of recent years, however, is clearly proving that after the proper performance of the modern complete operations, local recurrence ensues in only a small proportion of the cases, and that a large number of patients escape from any further manifestations of the disease.

The *rationale* of radical operations for mammary cancer is based mainly on two considerations: (1) The anatomy of the lymphatic system in this region; and (2) A study of the areas in which the disease reappears after incomplete operations. Before discussing the indications and contra-indications for the radical operation, brief reference must be made to its extent and nature. The following structures are removed in one continuous mass: the whole of the mammary gland and a large portion of the overlying skin; both pectoral muscles, excepting the clavicular fibres of the pectoralis major; the whole lymphatic area, including the fascia and fat from the epigastric region below to the clavicle above and to the commencement of the brachial artery laterally. The incision extends from just above the insertion of the pectoralis major, includes a large ellipse of skin, and terminates in the epigastrium midway between the costal margin and the umbilicus.

This is obviously an extensive and very complete operation, but the results fully justify it. One would point out strongly that it is not a formidable operation; there are some who object to it on the grounds that it involves great shock, great risk, and that it is unnecessary. The last argument is scarcely a serious one when we consider the nature of the disease with which we are dealing. The other arguments do not hold good in practice.

I have performed this operation during the last ten years in all cases in which there was a reasonable prospect of eradicating the disease, and can testify to the comparative ease with which it can be carried out. The usual duration of the operation is from 40 to 50 minutes; there is rarely marked shock or collapse afterwards if the hæmorrhage be kept at a minimum; and the patient is able to get about at the end of a week or ten days; with proper after-treatment the movements of the arm are scarcely impaired. Finally, the prospects of the patients are infinitely better than if any of the less extensive operations had been performed.

Indications for Operation.—In many cases it is at once clear that operation is the right and proper course; in others it is equally clear that any operation would be futile or even harmful; but there are a great many borderland or doubtful cases, in which every aspect must be carefully considered before a decision is reached.

The best subjects for operation are middle-aged, comparatively thin women, with sound viscera, who have small growths in the outer quadrant of the breast, with slight or no palpable enlargement of the axillary glands. Bad subjects are those who are young and have large breasts, those who are stout and plethoric, the alcoholics, diabetics, bronchitics, those with feeble hearts or diseased kidneys, those who are elderly and have little power of resistance.

The following local conditions exclude any attempt at radical operation: (1) Fixation of the growth to the thorax; (2) Extensive involvement of the skin, either in the form of a brawny induration or of multiple widely-scattered nodules; (3) Implication of the axillary vessels or nerves.

Enlargement of the supraclavicular glands is usually held as an indication

that the disease has gained too strong a grip upon the patient, and that operation for palliative purposes only is possible. Some surgeons have practised operations in such cases, and have reported a few successful results. One would say, therefore, that in the majority of cases this complication renders any extensive operation useless, but that in certain cases, with very slight involvement of these glands, extirpation may be attempted.

Atrophic Scirrhus should always be operated upon, if there is any reasonable prospect of completely removing the disease, unless the patient be very old or very feeble. It is true that such cases may go on for a very long time without serious trouble, but ultimately most of them die of internal deposits; on the other hand, if operation be done thoroughly, there is an exceptionally good chance that a permanent cure may result.

Visceral and Bony Deposits of course negate any possibility of cure; very careful search should be made for these before advising operation, for they are easily overlooked when showing themselves as vague "rheumatic" pains about the limbs or spine, slight pleural effusions, etc.

Diabetes, Cirrhosis, and Renal Disease are formidable complications. The advice of a physician should at once be taken, and, if diabetes be present, a quantitative examination of the sugar in the urine be made. The question resolves itself into one of the successful performance of an operation under unusual difficulties, and in this respect we are now in a much improved condition. Sepsis, which formerly represented the main danger of diabetes, should nowadays be an almost negligible factor, whilst the precautions which prevent or diminish shock are better known. In diabetics it is advisable to devote a short time to careful dietetic treatment before operation. The increased risk involved by the presence of these complications must be explained to the patient or to her friends, but considering that without operation we are leaving her to die, and to die probably sooner owing to the complication, operation will usually be desired in spite of the increased risk.

In old subjects, say patients over seventy, the question presents very special difficulties. To begin with, a large proportion of these patients will obstinately refuse any operation, even before such treatment has been mentioned, on the ground that they are too old and could not stand any operation. In such cases one can only point out emphatically that no decision should be made until the facts of the case have been carefully explained and thought over by the patient and her friends for two or three days. The first point is to estimate the patient's practical age, for many of them will be found to be for surgical purposes much younger or older than the actual age given. For this purpose a thorough examination must be made, special attention being paid to the heart, lungs, arteries, and urine. Secondly, a rough estimate must be made of the rate at which the tumour is growing and the length of time which is likely to elapse, if no operation be performed, before it causes the patient's death. Accuracy in a matter of this kind is obviously impossible, but with care and experience an approximate result may be obtained. Generally speaking, of course, these growths are very slow in old subjects, and the older the patient the slower the growth; in fact, in some it is obvious that the patients are far more likely to die from other causes before the growth is sufficiently advanced to cause them much trouble or to kill them. Thus most cases of the atrophic variety of scirrhus in patients over 70 are best left alone. Thirdly, we have to consider the risk, and this will depend on the general condition of the patient and the difficulty and duration of the operation. In the greater number of cases it will be advisable to limit the duration of the operation to twenty minutes or half an hour.

Pregnancy forms a very serious complication in cancer of the breast. In

considering the question of operation, two main facts present themselves—the rapidity with which mammary cancer grows during pregnancy and lactation, and the risk of abortion after the necessarily extensive operation. There are some who advise against operation owing to fear of disturbance of the pregnancy. But the indications are perfectly clear. To leave the patient means rapid increase, and probably fungation, of the growth, and early death; moreover, there is still a liability to miscarriage or non-survival of the child. On the other hand, miscarriage after removal of the breast occurs in certainly less than half of the cases. Pregnancy should therefore never be considered as an argument against operation when the growth is removable, but should be taken as demanding early and thorough operation.

The question of treatment in cases of *bilateral carcinoma* may at first sight suggest difficulties, but may be decided easily in the following way: Each breast is considered by itself, and a decision made as to whether operation would be advised for the disease in that particular breast, if the other breast were not affected. If one can answer in the affirmative as regards each breast individually, then operation for both sides should be recommended. If operation is decided upon, then the question arises as to whether both sides should be dealt with at the same time, or by two operations. In ordinary circumstances one would prefer to allow an interval of a fortnight or so to elapse between removal of the breasts, but several factors must be considered. There are some subjects whose physical powers would be dangerously taxed by two extensive operations in a short time; there are some who could not face the prospect of two separate operations; and there are those disappointing cases, which all surgeons encounter, in which the patient consents to two operations, but after the first refuses to allow the second to be performed. On the other hand, there are practical or placid women who have the moral courage, as well as the physical powers, to face two separate operations. If the breasts be removed at the same time, all the resources of surgical organization are called for; the work must be done as quickly as possible, though thoroughly, and above all things hæmorrhage must be reduced to a minimum. The best plan is to have a skilled assistant, who can ligature vessels and sew up the wound after removal of the first breast, whilst the surgeon proceeds to removal of the other. The time occupied in suturing the wounds can be reduced considerably by the use of Michel's sutures.

After-treatment.—Immediately the wound has healed, it is advisable to treat the entire operation area by means of exposure to x rays, with the idea of destroying any isolated cancer cells which may remain. Three full Sabouraud doses are given over a period of four weeks. In addition, wherever possible, careful examination of the patient should be made at regular intervals so as to detect any recurrence at the earliest possible moment.

PALLIATIVE OPERATIONS.—A great many cases of mammary carcinoma which come under notice are unfortunately obviously beyond the possibility of any radical cure; but in many of these cases a palliative operation may give much relief. These operations are performed to prolong life, to give relief to pain, to prevent fungation, and to make the patient more comfortable and happy during the time that remains to her.

Removal of the breast as a palliative operation is called for mainly in comparatively young subjects with large, rapidly growing tumours; such tumours often cause much pain, and are a source of great distress to the patient; and when fungation occurs this distress is greatly increased, and the sepsis which almost invariably follows rapidly shortens the patient's life.

The nature of the operation depends on the distribution of that portion of the disease which is causing trouble. In most cases a simple removal of the breast

and the most enlarged glands in the axilla is the operation for choice; any elaborate clearing of the axilla is usually inadvisable. In some cases, however, when pressure upon the axillary nerves by enlarged glands is likely, the axilla should be cleared up to the clavicle as in the "complete" operation. I would strongly insist on one point: in all palliative operations the skin flaps should be so cut that they can be united without difficulty, so that the wound heals by first intention. Unless this can be done I should advise against any operation, for I believe that more harm than good comes of leaving a large raw surface. The very object of the operation, palliation, is usually defeated by inability to completely close the wound; the long convalescence means much distress and disappointment to the patient, and growth often shows itself in the granulating wound, which then of course never closes.

Recurrent disease should be dealt with at once unless obviously irremovable. The most favourable recurrences are superficial nodules in the neighbourhood of the scar; if these are widely excised, no further recurrence usually occurs in that particular region. Large masses of recurrent growth adherent to the chest wall can seldom be dealt with successfully, and for these cases x-ray treatment should be carefully tried.

NON-OPERATIVE TREATMENT.—There is at the present time no remedy which can replace, or give any excuse for delay in, operation. Should the disease be obviously beyond operative treatment, nothing can produce any permanent effect on the progress of the disease.

The curious vagaries of cancer account for the supposed success of certain remedies, such as "violet leaves," "cinnamon bark," and "trypsin." If these remedies are given at a time when the tumour is about to undergo one of these curious pathological improvements, they gain the credit of having worked a marvellous cure.

Strong caustics are painful, dangerous, and excite suppuration. Electricity sometimes relieves pain, and encourages the patient, but is otherwise useless. x rays are undoubtedly useful in certain cases; they usually relieve pain, and can cause the disappearance of superficial nodules, and the temporary healing of superficial ulceration. There is probably no case in which they have effected a cure, and they have practically no effect on subcutaneous disease covered by healthy skin. Dermatitis may be caused if the rays are not skilfully applied; occasionally their use excites a sudden inflammatory condition and rapid increase of the growth.

The injection of Coley's fluid has produced a few undoubted cures in cases of inoperable sarcoma; in the great majority it fails, and its use is attended by marked constitutional disturbance and definite risk. For inoperable sarcoma this treatment may be considered, but in cases of carcinoma its use is scarcely justifiable under present conditions. (See also p. 154.)

Oophorectomy for irremovable mammary cancer has now received extensive trial, and the results are disappointing. There has probably been no case of true cure, but marked temporary improvement is said to have occurred in about 25 per cent of the cases which have been publicly reported. The best results have been obtained in patients between forty-five and fifty years of age; after fifty no good appears to follow the operation. The mortality amongst the published cases is about 6 per cent. The facts may be summed up as follows: In about 20 to 30 per cent of the cases definite relief and improvement appear to follow the operation; the probability of cure is remote; the mortality of the operation in these circumstances is about 6 per cent; chronic growths in patients between forty-five and fifty give the best results.

Medical Treatment of Inoperable Carcinoma (see also CANCER, GENERAL TREATMENT OF, p. 154).—Much may be done to relieve those suffering from inoperable

cancer. The medical man must use his discretion as to the amount of encouragement and hope that he gives the patient.

Pain will usually necessitate the use of morphia; bromides, veronal, and acetyl-salicylic acid give a certain amount of relief in the earlier stages, but morphia usually becomes necessary: if so, it should be given in sufficiently large doses to completely relieve the pain, and steadily increasing doses will be necessary, and are well borne.

The most important point in the local treatment is asepsis; for if the growth ulcerates and becomes septic, the patient's life is considerably shortened. Antiseptic dressings are regularly applied, and the ulcerating surface should be occasionally painted over with 1-5 carbolic acid. If the surface should become very foul, hydrogen peroxide is the best application. If the growth should cause much pain, one of the following applications recommended by Sheild should be used: (1) Citric acid, 2 dr. to 8 oz. of water; (2) Warm poultices of fresh conium leaves; (3) Freshly prepared succus conii (B.P. 1878) and lanolin, equal parts of; (4) Cocaine ointments.

Hæmorrhage from an ulcerating surface should be treated with adrenalin solution, or hamamelis lotion, and firm pressure.

Lymphatic Œdema of the Arm.—This is one of the most distressing results of mammary carcinoma; it is often associated with severe pain, due to the involvement of nerves by growth in the subclavian triangle or high in the axilla. Relief is usually afforded by massage and firm bandaging; if flexion at the elbow is not interfered with, a sling should be worn. In some cases thyroid extract causes marked diminution in the œdema of the arm, appearing to act as a lymphagogue. In cases of very severe pain, the possibility of relief by operation arises. The pain may sometimes be cured by removal of glands pressing on the nerves; it may be relieved by division of the nerve trunks, a comparatively simple proceeding, which, however, leaves a paralyzed and still œdematous arm.

Lymphangioplasty is indicated in certain cases, and sometimes causes considerable diminution of the œdema. For details of the operation, Mr. Sampson Handley's Hunterian Lectures (*B.M.J.*, April, 1910) should be consulted.

In cases of agonizing pain, in which life is scarcely tolerable, removal of the limb by a circular amputation just below the shoulder should be considered; in suitable cases this may give great relief. Removal of the whole fore-quarter has occasionally been performed, but is seldom justifiable.

Doubtful Tumours.—The use of a grooved needle or small trochar for the diagnosis of doubtful swellings of the breast is to be most strongly condemned; it is both painful and alarming to the patient, and may be very misleading to the surgeon. It is used as a rule to discover whether there is fluid in the swelling; but in thick-walled cysts it frequently fails to enter the cyst, and leaves one with the impression that the swelling is solid, whilst if fluid is drawn off it tells us nothing of the nature of the cyst; the cyst may contain intracystic growths or may be connected with a small malignant growth. In the case of solid tumours also the grooved needle gives us no information of any kind, and it seems probable that the puncture of a malignant growth may stir it to increased activity. The grooved needle is in fact one of the most dangerous instruments ever invented. Exploratory incision should be the routine treatment for all doubtful swellings; delay is not permissible, for experience shows that the greater number of "doubtful swellings" prove to be malignant. In nearly all cases, the nature of the tumour becomes at once apparent upon incision, but in some the microscopical evidence must be awaited. Where it is desirable to proceed to the full operation at once if the growth proves malignant, arrangements can be made to receive an immediate report from the pathologist; thus, in a case upon which I operated recently, the microscopical report was

received five minutes after the removal of a portion of the growth, and the radical operation was proceeded with at once: the aid of a skilled pathologist is necessary.

T. Crisp English.

BREASTS, HYPERTROPHY OF THE.—True hypertrophy of the breasts is uncommon, commences generally at puberty, and is usually bilateral.

TREATMENT.—In a small proportion of the cases, arrest or diminution of the condition may be brought about by the prolonged application of firm pressure, and the internal administration of iodides. In some cases the hypertrophy is progressive in spite of medical treatment, and partial or complete removal of the breasts, which are functionless, becomes necessary. There are no special difficulties about these operations if they are carefully planned and the hæmorrhage is efficiently dealt with.

T. Crisp English.

BREATH, OFFENSIVE.—Local causes, such as carious teeth, pyorrhœa, chronic enlargement of the tonsils, etc., should first be looked for. Assuming these to be absent, attention should be paid to the stomach and bowels. The diet should be regulated on the same lines as for chronic CONSTIPATION (q.v.), and a mild aloetic pill, or a grain or two of cascara along with $\frac{1}{10}$ gr. of calomel, administered every night. If the tongue be furred, the same remedies should be administered as in chronic GASTRITIS (q.v.), and exercise in the open air enjoined. The condition can always be masked if necessary by occasionally sucking an aromatic “cachou,” or a tablet of euthymol.

Robert Hutchison.

BRIGHT'S DISEASE.—(See NEPHRITIS.)

BROMIDROSIS.—(See PERSPIRATION, OFFENSIVE.)

BRONCHI, FOREIGN BODIES IN.—(See FOREIGN BODIES IN THE AIR-PASSAGES AND ŒSOPHAGUS.)

BRONCHIECTASIS.—Before studying the treatment of this affection it is necessary to understand its varieties and etiology, and also the results or complications which may supervene; for it is these that need attention rather than the actual condition, which admits of little if any amelioration, and which, if robbed of these consequences, is compatible with a fairly healthy, useful, and active life.

1. A congenital form occurs (very rare). It is always unilateral, and the other lung hypertrophies, so taking on the work of both.

2. The form due to more or less extensive fibrosis of lung, consequent upon interstitial or unresolved pneumonia or bronchopneumonia, pleurisy, or empyema. This, too, is often unilateral, the other lung hypertrophies, and the patients are often in good health but for attacks of bronchial catarrh, or some of the complications mentioned below.

3. The form occurring with chronic bronchitis and emphysema, or in chronic cases of pulmonary tubercle. Here the treatment is chiefly that of the affection causing it, plus that of complications as stated.

4. The form due to the impaction of a foreign body in a bronchus, or to pressure of an aneurysm, or other tumour, upon one of the tubes. The tubes beyond the obstruction, softened and inflamed by the retained, often decomposed and fetid, secretion, dilate, and complications are more likely to occur than in any other form.

5. Acute dilatation occurring as the result of excessively frequent and prolonged paroxysms of coughing, usually in the course of pertussis. Treatment of the

cough and accompanying bronchitis, with general tonics, we have seen result, apparently, in the complete disappearance of this condition.

It will be seen that in many instances the appropriate treatment will be directed towards the disease causing bronchial dilatation, or in the course of which it occurs; whilst in others only general tonic and hygienic measures are needed. It is the consequences which are most to be dreaded. They are:—

1. Hæmorrhage—(occurred in 14 out of 35 cases—Fowler).
2. Bronchitis, very liable to recur, often runs a febrile course, and is not uncommonly accompanied by patches of pneumonia.
3. Retention with decomposition of sputum, which is most to be feared, as it may give rise to:—
 - i. Fœtid bronchitis.
 - ii. Ulceration of tubes.
 - iii. Gangrene of lung.
 - iv. Septic absorption, with secondary abscesses (brain).
 - v. Empyema.

Hæmorrhage is not generally profuse, and the usual treatment for hæmoptysis (*q.v.*) is applicable in such cases. The recurrent bronchitis needs special care, because of the damaged state of the lung, and the likelihood of the attacks running on to a pneumonia, or becoming fœtid; otherwise their treatment does not differ from that of ordinary cases. The chief aim is to prevent the retention and decomposition of sputa, and correct the fœtid and septic nature of the secretions. The following points are important:—

Encourage the emptying of the dilated tubes, by mechanical means if natural efforts of coughing are ineffectual. This can be done by inverting the patient, getting him to assume the genu-pectoral position, or lean well over the edge of the bed so that his head nearly touches the floor. In children, emetics are often useful to help in the expulsion of the accumulated secretions, or firm rubbings and pressure of the chest with the hands. These methods are directed towards prevention of decomposition, but are equally important where fœtor is present. In such a case we must add the use of antiseptics. These may be given by the mouth, inhaled, or introduced by intratracheal injections, or they have even been injected directly into the cavity of the dilated tube through the chest wall with a hypodermic syringe.

Internally, the best remedy is creosote (2 to 3 min. given in capsule twice a day) or guaiacol (5 to 6 min. twice daily). Oil of garlic (1 to 2 min. in capsule twice a day) is also often very effectual.

For inhalations, the formulæ given below will be found useful. But by far the most successful way of getting the secretions sweet is by the inhalation of creosote, vaporized by heat. For this purpose the patient is put into a small chamber, rendered as air-tight as possible, and a metal dish full of ordinary commercial creosote is placed on a tripod under which a small spirit lamp is arranged. The vapour comes off in dense, whitish fumes. These fumes are very irritating, so that the eyes of the patient must be protected by watch-glasses and strapping, and his nostrils plugged with cotton-wool, whilst he is instructed to breathe through his mouth. Salivation, profuse coughing, and expectoration result; usually patients are not able to tolerate a sitting longer than from ten to twenty or twenty-five minutes, which should be repeated daily. We know of no more efficacious means of reducing the fœtor of the expectoration.

Intratracheal injections are usually composed of: menthol 10 per cent, guaiacol 2 per cent, olive oil 88 per cent, and about a drachm of this mixture is introduced, by means of a tube and syringe, into the trachea twice daily. Care must be taken, during the injection, that the patient is lying on the side into

which it is wished that the remedy should go, in order that it may gravitate into that bronchus.

Lastly, it is necessary to mention that some very chronic bronchiectatic cavities have been treated by incision and drainage. The results are not encouraging. The cavity cannot contract and become obliterated, and thus a permanent sinus usually results. More recently, further operative measures have been used. Where there has been a single, more or less limited, dilatation of a tube, excision has been practised with success; and where the dilatation (and other damage to the lung) has been due to a foreign body, operation has been resorted to for its removal.

BRONCHITIS, ACUTE.—Treatment should be directed to the relief of the congestion of the bronchial mucous membrane, to the increase of the secretion of the bronchial mucus, to the prevention of the spread of the inflammation to the finer bronchial tubes, to lessening the patient's discomfort, and to combating complications. The patient should be kept in one room, the temperature of which should be from 60° to 65° F.; the air may be moistened by a steam kettle, to the water in which may be added some aromatic such as oil of eucalyptus (5 min. to the pint), compound tincture of benzoin (1 dr. to the pint), or phenol ($\frac{1}{2}$ dr. to the pint). If the attack be severe, the patient should be confined to bed, propped up by pillows or a bed-rest; the clothing should be warm but light; a Shetland-wool jacket or one made of Gamgee tissue is useful for this purpose.

In the earlier stages the diet should be fluid and warm; later, solids may be added as the appetite returns. Stimulants may be given in small quantities if the patient is accustomed to them; otherwise they should be reserved until special indications for their use arise.

Hot baths, vapour baths, and Turkish baths are frequently employed at the onset of acute bronchitis; they promote diaphoresis and relieve the bronchial congestion, but great care has to be exercised to avoid a subsequent chill. The employment of drugs depends upon the stage of the disease and the condition of the patient. Before the bronchial secretion is established, ipecacuanha, antimony, or aconite, combined with diaphoretics and purgatives, are useful:—

R Vini Ipecacuanhæ \mathfrak{z} ij
Spiritus Ætheris Nitrosi $\mathfrak{a}\mathfrak{a}$ \mathfrak{m} x | Liquoris Ammonii Acetatis \mathfrak{z} ij
Aque Camphoræ q.s. ad \mathfrak{z} j
Every four hours.

Or,

R Pulveris Ipecacuanhæ gr j | Potassii Nitratis gr v
Ft. chart. No. i Every four hours.

Vinum antimoniale may be substituted for the vin. ipecac. in young adults.

It is a very valuable drug in bronchitis, but its effect on the circulation should be observed. Aconite may be given if the pulse is full and bounding; one half minim of the tincture in a little water should be administered hourly for six or eight doses, the effect being carefully watched.

In the early stage, sleep may be secured and much relief given by pulv. ipecac. co. 10 gr., combined, if an aperient be required, with one or two grains of calomel, to be followed on the following morning by a dose of Apenta water or a seidlitz powder. At this stage stimulating applications to the chest relieve the sensation of soreness. Lin. terebinth. aceticum (B.P.) or lin. camph. co. (B.P.) may be employed, or portions of a mustard leaf may be applied to the chest. Poultices are seldom necessary, and may do harm from the weight and the difficulty of changing them without chilling the patient. If the cough at this stage is very troublesome, and is not controlled by demulcents such as barley-water, or liquorice or marsh mallow lozenges, inhalations may be of use :—

R	Mentholis	gr xij	Alcohol 90 %	3j
	Chloroformi	3j		

20 min. in a pint of hot water for the inhalation.

In some cases, where there seems to be an asthmatic element with marked bronchial obstruction, relief may be given by belladonna or stramonium combined with iodide of potash :—

R	Tincturæ Belladonnæ	℥xij	Potassii Bicarbonatis	gr xv
	Potassii Iodidi		Aquæ Camphoræ	q.s. ad 3j
	Ammonii Carbonatis	āā gr iij		

Three or four times daily.

Careful watch must be kept for toxic effects of the belladonna or iodide, which in some patients appear very early. In this type of case, where there is not much bronchial secretion, apomorphine may be of great use :—

R Syrupi Apomorphinæ Hydrochloratis (B.P.C.)
A teaspoonful every two hours until the bronchial secretion is established.

When the bronchial mucous membrane begins to secrete and sputum appears, stimulant expectorants should be prescribed :—

R	Ammonii Carbonatis	gr iv	Tincturæ Scillæ	℥viii
	Vini Ipecacuanhæ	℥v	Infusi Senegæ	q.s. ad 3j

Every four hours.

During convalescence general tonics and change of air are of great value.

It is best to avoid opium as much as possible; sometimes it is of great value at the commencement of an attack when there is an irritating but useless cough which keeps the patient awake, and again at the end of an attack when the expectoration is free but persistent. In the former case pulv. ipecac. et opii is probably the best preparation, in the latter tinct. opii camph. :—

R	Aceti Scillæ	℥xii	Spiritus Chloroformi	℥x
	Tincturæ Opii Camphoratæ	℥xxx	Infusi Cascarillæ (2·5 per cent)	q.s. ad 3j

Thrice daily.

Opium is contra-indicated when there is any degree of cyanosis. Sleep is most important at all stages of the disease; if it cannot be secured by simple measures such as hot sponging, and hot fluid food with or without alcohol, recourse must be had to drugs. Paraldehyde is perhaps the safest, but is nauseous :—

R	Paraldehydi	3j	Alcoholis	3ij
	Glycerini	℥xl	Aquæ Cinnamomi	q.s. ad 3j

The draught to be taken at bedtime.

Sulphonal 20 to 30 gr., trional 20 to 30 gr., veronal 5 to 10 gr., in cachets, are safe but not always successful. If opium seems necessary, it is best given in the form of morphia ($\frac{1}{8}$ to $\frac{1}{4}$ gr.) hypodermically, in combination with atropine ($\frac{1}{200}$ to $\frac{1}{150}$ gr.).

The occurrence of cardiac failure must be met by the exhibition of appropriate remedies (see CONGESTION, PULMONARY). *Cecil Wall.*

BRONCHITIS, CHRONIC.—When bronchitis has become chronic, and is associated with emphysema, as is then almost invariably the case, treatment can be directed only towards the relief of symptoms and the prevention of the recurrent acute attacks which aggravate the condition.

Specific Treatment.—Active immunization of the patient by vaccines prepared from organisms isolated from the sputum has been practised in cases of chronic bronchitis. Satisfactory results have been recorded, but the method has not yet passed out of the experimental stage. The use of vaccines is not unattended by danger; they should be prescribed only by those who have had special experience, and the tentative employment of stock vaccines is most undesirable. (See SPECIFIC THERAPY.)

General and Preventive Treatment.—The etiology of the disease in each patient must be considered, and, so far as is possible, steps should be taken to remove the cause. If the patient's occupation be dusty, or if it involve frequent exposure to inclement weather, or otherwise seem deleterious, the possibility of a change should be considered; if some other disease be the underlying cause, e.g., spasmodic asthma, rickets or adenoids (in children), fibrosis or tuberculosis of the lungs, heart disease, gout, obesity, chronic kidney disease, etc., appropriate treatment should be adopted. In all cases of chronic bronchitis, special attention should be paid to the condition of the nose. Gross abnormalities, such as polypi or a deviated septum, may aggravate, if they do not cause, the bronchitis, and minor abnormalities, by predisposing to recurrent coryza, frequently lead to exacerbations.

Patients with chronic bronchitis are much affected by sudden changes of temperature, and the details of their daily life should be arranged accordingly: the clothing should be warm yet light, conditions best fulfilled by flannel or Jaeger underclothing; "chest protectors" are cumbersome, difficult to keep clean, and unnecessary. A light shawl should be the constant companion of a lady in evening dress. The extremities, especially in children, should be warmly clad.

The living-rooms should be kept warm, but not too warm, lest the change of temperature on leaving them should exercise a bad effect; efficient ventilation is most important; the foul air of crowded assemblies, close railway carriages, and the like are frequent sources of danger. Those liable to bronchitis should be careful to avoid contact with those in the acute stage of coryza. To many patients a fire in the bedroom in the winter is a necessity rather than a luxury; closed stoves, gas fires, and naked gas flames in the room generally prove harmful. Close confinement to the house as a routine measure is very much to be deprecated; daily exercise in the open air with reasonable precautions to prevent chills is not merely the best means to prevent recurrent attacks of acute bronchitis, but also the safest guard against dyspepsia, obesity, and the other ills of a sedentary life. Careful attention to such details as these will add much to the comfort of a sufferer from chronic bronchitis.

To those who can afford it, the approach of winter will suggest migration to a warmer climate. Many places on the south coast of England, in the French or Italian Riviera, Sicily, Algiers, or Egypt have climatic advantages, but it must always be remembered that the majority of patients are unable to obtain the

same care and comfort when travelling that they can enjoy at home. In selecting a winter resort, the individual should receive at least as much attention as the bronchitis, and any associated conditions must be taken into careful consideration.

Drug Treatment.—The treatment of chronic bronchitis by drugs must be determined by symptoms and by associated conditions. If an attack of acute bronchitis supervenes, as is often the case, it should be treated as described under that heading.

When the cough is chronic and the sputa abundant and easily expectorated, the aim of the treatment should be to aid the expulsion of the secretion, to stimulate the respiratory centre, to strengthen the right ventricle, and, if necessary, to procure sleep. A nutritious diet, rich in fatty foodstuffs, is generally indicated; often it is desirable to supplement this with cod-liver oil or other easily digested fat, e.g. :—

R Extracti Malti cum Oleo Morrhue.

Two teaspoonfuls to be taken twice a day after meals.

An old and useful prescription in an ordinary case of chronic bronchitis, with moderate secretion, is :—

R Tincturæ Nucis Vomice	℥ xij	Spiritus Chloroformi	℥ x
Ammonii Carbonatis	gr v	Infusi Senegæ	q.s. ad 3j
Tincturæ Scillæ	℥ viij		

Three or four times a day.

Senega is very useful, but unfortunately it is very nauseous; solutions containing it froth very readily, hence the bottle should not be shaken. Infusions of serpentary, cloves, or gentian may be substituted for the senega, but are not as efficient.

Nux vomica has been called the best hypnotic in chronic bronchitis; often it acts like a charm. In old people it sometimes causes great irritability of the bladder; in this case tincture of belladonna may be substituted for it in the above prescription. If the right ventricle shows signs of failure, the addition of tincture of digitalis v-x min. to the mixture is advisable. Squill is a very valuable stimulant expectorant, and also aids the action of the heart in the same way as digitalis. Another useful and palatable cough mixture is :—

R Syrupi Scillæ		Aquæ Chloroformi	q.s. ad 3j
Acidî Hydrobromici diluti	aa 3ss		

Three times daily.

Or,

R Oxymellis Scillæ (B.P.)	3ss	Aquæ Anisi	q.s. ad 3j
Vini Ipecacuanhæ	℥ v		

Three or four times daily.

When the sputum is scanty and tenacious, potassium iodide is of great value :—

R Potassii Iodidi	gr iiij	Potassii Bicarbonatis	gr x
Ammonii Carbonatis	gr iv	Aquæ Camphoræ	q.s. ad 3j

Three times a day after meals.

When there is an asthmatic element, belladonna or stramonium should be added to the mixture :—

R Potassii Iodidi	gr iiij	Extracti Stramonii	gr ½
{ Ammonii Carbonatis	gr iv	Extracti Glycyrrhizæ	gr ij
{ Potassii Bicarbonatis	gr xv	Aquæ	q.s. ad 3j

Thrice daily.

Treatment of Cough.—Cough is the symptom of which the patient will complain most; generally speaking it is useful, serving to keep the bronchial

tubes empty of secretion. In such circumstances the cough should be encouraged, though steps may be taken to relieve the more distressing features; in most cases it is sufficient to prescribe some simple lozenge or linctus to be used in conjunction with the general treatment outlined above. The trochiscus glycyrrhizæ of the Brompton Hospital is well known :—

R Extracti Glycyrrhizæ	gr iiij	Acaciæ	gr ij
Olei Anisi	℥ss	Sacchari	gr x

A lozenge to be taken occasionally.

Or the trochiscus gummi eucalypti of the B.P. may be employed, with or without the addition of menthol gr. $\frac{1}{4}$. Many similar lozenges may be obtained. The most serviceable linctus is :—

R Tincturæ Opii Camphoratæ	Syrupi Tolutani	āā ℥ xx
Oxymellis Scillæ (B.P.)		

One teaspoonful occasionally.

Another simple linctus is :—

R Syrupi Scillæ	Syrupi Papaveris	
Syrupi Limonis	Syrupi Tolutani	āā ℥ xv

One teaspoonful occasionally.

For the morning cough a hot alkaline drink taken before rising in the morning is often of extreme value. A wineglassful of Ems Water (Krähnenchen) may be taken in half a tumblerful of warm milk, or the following mixture with an equal quantity of hot milk or water :—

R Sodii Bicarbonatis	gr xv	Spiritus Chloroformi	℥ v
Sodii Chloridi	gr v	Aquæ Anisi	q.s. ad ℥ j

If, on the other hand, the cough be useless and harassing, it may be wise to use more sedative remedies, especially when sleep is disturbed :—

R Liq. Morphinæ Hydrochloridi		Spiritus Chloroformi	℥ iv
	1 per cent ℥ vj	Syrupi Limonis	℥ xxx
Aquæ Laurocerasi (B.P.) vel Aquæ Amygdalæ Amaræ	℥ viij	Glycerini	q.s. ad ℥ i

Occasionally.

Or,

R Heroini Hydrochloridi	gr $\frac{1}{8}$	Tincturæ Pruni Virginianæ (B.P.)	℥ x
Terpini Hydratis	gr j	Glycerini	ad ℥ j

Occasionally.

For a troublesome, ineffectual night cough :—

R Pilulæ Ipecacuanhæ c. Scilla (B.P.)	gr iv
---------------------------------------	-------

The pill to be taken at bedtime.

Or,

R Morphinæ Hydrochloridi	gr $\frac{1}{8}$	Pilulæ Aloes et Myrrhæ	gr ij
Atropinæ Sulphatis	gr $\frac{1}{80}$		

The pill to be taken at bedtime.

A long-continued, distressing, ineffectual cough is often much relieved by ammonium chloride. It may be prescribed in the form of a lozenge containing :—

R Ammonii Chloridi		Extracti Glycyrrhizæ	āā gr. iiij
--------------------	--	----------------------	-------------

Or a fruit basis may be substituted for the liquorice. If a solution be preferred :—

R Ammonii Chloridi	gr xv	Spiritus Chloroformi	℥ x
Tincturæ Limonis	℥ j	Aquæ	q.s. ad ℥ iij

To be sipped frequently.

Inhalation of the mixed vapours of hydrochloric acid and ammonia is a common mode of administration of the drug. Several forms of apparatus suitable for the purpose can be obtained. Steam inhalations often prove of great value ;

water at a temperature of 140° F. should be used in a special apparatus, and any of the following may be added to each pint :—

R Tincturæ Benzoini Compositæ ʒj

Or,

R Olei Eucalypti	Tincturæ Benzoini Co.	āā ℥xx
Olei Pini Sylvestris		

Or,

R Mentholis	gr ij	Spiritus Coloniensis	q.s. ad ʒj
Chloroformi	℥x		

Insomnia.—The sleeplessness of chronic bronchitis often disappears under general treatment, without special hypnotics. In a very bad attack it is necessary for the patient to keep awake in order by voluntary effort to assist the exhausted respiratory centre.

If strychnine (probably the best hypnotic in chronic bronchitis), digitalis, carbonate of ammonia, and belladonna have failed to induce sleep, recourse must be had to other drugs.

Alcohol.—The best brandy or whisky obtainable should be used. Many of the cheaper spirits given in large doses are poisonous. The great advantage of brandy or whisky as a hypnotic is that it is quickly eliminated, and it is not cumulative in its action. Starting with small doses, $\frac{1}{2}$ to 1 oz., about an hour before the time at which the patient usually goes to sleep, the quantity may be gradually increased. Its effect varies much in different patients, and it is only by trial that its value can be estimated.

If it (a) Produces sleep, and lessens restlessness; (b) Lessens frequency of respirations; (c) Lessens frequency of pulse; (d) Lowers temperature; (e) Makes the tongue less dry—it may be safely continued.

At present, for many reasons, the tide is running strongly against the use of alcohol; but in suitable cases it is, beyond doubt, valuable and effective.

The Bromides.—These must be used in full doses to have any chance of success.

R Sodii Bromidi		Tincturæ Hyoscyami	℥xx
Ammonii Bromidi	āā gr xx	Aquæ Camphoræ	q.s. ad ʒj

If this draught fail within one and a half hours, it should be repeated. Some such combination, which can be varied in many ways, is safe, and often answers.

Paraldehyde, in doses of 1 to 2 dr., induces quiet sleep, and has very few unpleasant after-effects, but its taste and smell are intolerable to many patients. The adjuvants usually added do not get rid of this disadvantage entirely. Two formulæ are :—

R Paraldehydi	ʒj	Extracti Glycyrrhizæ Liquidī (B.P.)	ʒiss
Syrupi Aurantii	℥xv	Aquæ	q.s. ad ʒj
	M. Ft. haustus.		

Or,

R Paraldehydi	ʒj	Extracti Glycyrrhizæ Liquidī (B.P.)	ʒj
Olei Amygdalæ Ess. (sine Acido		Syrupi	ʒss
Hydrocyanico)	℥iss	Aquæ	q.s. ad ʒij
	M. Ft. haustus.		

Martindale.

Sulphonal 20 to 30 gr., trional 20 to 30 gr., veronal 3 to 7 gr., in tablets or cachets, are worth trying.

Opium.—The well-recognized disadvantages of opium or morphia in chronic bronchitis are that while, with very few exceptions, they may be relied on to produce sleep, (a) They are cumulative, and not easily eliminated; (b) They depress and lull the respiratory centre at a time when its activity is most

essential; (c) They upset the digestive process. These dangers are real, but may be much exaggerated, and should not paralyze the practitioner in face of persistent insomnia. A few hours' steady sleep is often the turning-point in a bad case of bronchitis.

The simplest combination, the old-fashioned pulv. ipecac. et opii, may be given in doses of 5 to 15 gr., with or without some alcohol.

Morphia may be given hypodermically, guarded by small doses of atropine, which lessen the effect on the respiratory centre.

R. Morphinæ Hydrochloridi gr $\frac{1}{4}$ - $\frac{1}{2}$ | Atropinæ Sulphatis gr $\frac{1}{100}$
Ft. injectio hypodermica.

One rarely sees any trouble from these doses. The atropine, besides its effect on the respiratory centre, diminishes the tendency to sweating. There are cases when everything fails, but in the majority, with care, safe sleep may be induced.

Cardiac Failure.—The most frequent and dangerous complication of chronic bronchitis is cardiac failure; œdema and congestion of the lungs are superadded to the bronchitis, and demand special treatment. (See CONGESTION, PULMONARY, and ŒDEMA.)
Cecil Wall.

BRONCHOPNEUMONIA, CATARRHAL.—(See also BRONCHITIS, and PNEUMONIA.) With the differential diagnosis between this affection and the croupous form we shall not deal.

It is, however, necessary to emphasize the following points:—

1. That catarrhal pneumonia is associated almost invariably with—practically is an extension from—bronchitis.

2. There is usually as much disseminated collapse as there is patchy consolidation of lung.

3. It is seen frequently in connection with diseases characterized by pulmonary catarrh, such as measles, pertussis, etc., and also in debilitated, rachitic, and unhealthy children.

4. It is more often followed by imperfect resolution, resulting in permanent damage to the lung.

As regards treatment, it must be remembered that, the affection being as it were a combination of bronchitis and pneumonia, with collapse, many of the methods applicable in these two conditions are frequently useful here. It may be impossible to say where bronchitis ends and pneumonia begins, and the treatment is simply that of acute bronchitis; whilst in other cases, the usually discrete, consolidated areas spread and coalesce until the condition is one of extensive pneumonia, complicated by a more or less diffuse bronchitis. We will, however, take an ordinary case. The indications for treatment will be:—

1. To relieve the evident difficulty of breathing, by liquefying and expelling the tenacious bronchial secretion; that is, treating the bronchitis.

2. To prevent extension of pneumonia and collapse.

3. To support the general strength and cardiac action.

1. *To Remove Excretion*—In adults, expectorants, such as the carbonate and chloride of ammonium, squills, and copious hot alkaline drinks, or the inhalation of steam, are most useful. In children, steam inhalation will be most reliable, or better still, getting them to take frequently-repeated drinks of milk and lime water, weak broth, or some other liquid, but always hot. In their case it is generally necessary to cause vomiting in order to get a proper emptying of the bronchial tubes: 10 to 20 gr. of powdered ipecacuanha (or 1 dr. of the tincture) may be used from time to time; but its depressing effect must be carefully watched, and it cannot often be repeated. Cupric sulphate is a very reliable and rapid emetic, without the depressing effect of ipecacuanha

on the heart. In all cases it must be remembered that expectoration, vomiting, or absorption must get rid of secretion as fast as it is made, or the tubes will become more and more blocked, with all that that means in dyspnoea, cyanosis, etc. It is useless, and even harmful, to promote a copious, watery secretion, without the patient having the power, or being stimulated, to get rid of it. There is not the necessity, so marked in the croupous form, for avoiding unnecessary movement; and, especially in children, frequent examinations of the chest, changes of position, brisk rubbing and squeezing of the chest wall, are most helpful means of stimulating expectoration.

N.B.—It must be distinctly understood that steam inhalation is recommended only when the secretion is scanty, is never to be used continuously in the old-fashioned way, and must always be discontinued when the secretions increase or if the slightest cyanosis is noticed.

2. *To Limit Extension of Consolidation and Collapse.*—Active local measures, such as leeching, cupping, etc., often so useful in the croupous form, are not attended by such good results in these cases. In the majority all that is necessary is to keep the patient very warm by the application of a cotton-wool jacket. Where the signs in the lungs are widespread, accompanied by great dyspnoea, retraction of ribs and cyanosis, active interference is necessary. Collapse goes hand in hand with consolidation in such cases; the symptoms (dyspnoea, etc.) are due as much to one as to the other, and our treatment must be directed to opening up collapsed air-cells quite as much as to preventing a few more small areas of consolidation. Application of cold to the chest has been recommended for this purpose, and may take the form of ice cloths, ice packs, cold bath, or douching. It has the twofold effect of lowering temperature and causing deeper respiratory movements calculated to inflate collapsed areas. Such methods are often attended by rapid and most beneficial results. It must, however, be laid down most strongly that such treatment is not unattended by risk of general collapse and heart failure, the patient becoming pallid and cold, with a small pulse. The good effects are seen in lowered temperature, deeper and easier breathing, and improving colour (less cyanosis). We think even better results are seen from an almost opposite line of treatment, viz., the hot mustard bath, accompanied by vigorous rubbing and squeezing of the chest while the child is in it. The water should be as hot as can be borne by the nurse's hand, and a good tablespoonful of mustard added; the child should be immersed to the shoulders for one to three minutes, vigorously rubbed, rapidly dried, and again covered in cotton-wool and blanket; the whole thing to be done before a good fire. Usually the respirations are much easier and deeper, and this effect can be increased by dashing cold water on the face and neck while the child is in the hot bath.

3. *To Maintain Strength and Cardiac Action.*—The fever is not so high, nor is the toxæmia so great, as in the croupous form, and the imminent danger of cardiac failure in *that* form is replaced in this by a failure of respiration, begotten of choked bronchial tubes and collapsed lung; though of course such a condition tends to cause cardiac failure eventually.

For the maintenance of the general strength food is of the greatest importance; it should be given frequently in liquid form, in small quantities, and is better given hot so as to stimulate secretion.

As a stimulant we prefer strychnine, because of its action on the respiratory centre as well as on the heart. Oxygen is rarely of much use, as it cannot get beyond the choked tubes. Digitalis is often helpful, as are also ether and caffeine. The same remark must be made as in speaking of stimulating drugs in croupous pneumonia, that in many cases to do any good at all they must be given under the skin.

Alcoholic stimulants are sometimes needed, and when used should be given in hot milk and water (10 to 20 drops every three hours will be enough for an infant). In some cases, where there is gastric intolerance, it is better to give stimulant and nourishment by the bowel for a time.

The *after-treatment* in bronchopneumonia is, without doubt, of far greater importance than in the croupous form. The collapsed and inflamed condition of the lungs, and the frequently unhealthy and generally debilitated state of the little patients, cause resolution to be slow and often imperfect; and one sees more permanently damaged, fibroid, and contracted lungs as the result of bronchopneumonia than from any other cause. In adults the risk of the supervention of pulmonary tubercle must be borne in mind. It is therefore important, in order to obtain as full and early a recovery of the lungs as may be, to get such cases into absolutely pure air as soon as possible, and to teach them systematic gymnastic and deep-breathing exercises. General tonic treatment, with abundance of good food, is also important.

RESPIRATORY STIMULANT IN BRONCHOPNEUMONIA.

M. Fiat mistura. One teaspoonful three or four times a day for a child under ten years. *W. J. Hadley.*

BRONCHOSCOPY.—(See FOREIGN BODIES IN THE AIR-PASSAGES.)

BULIMIA.—This condition should be treated by first removing the cause if it is known, secondly regulating the quantity of food, and thirdly allaying the craving by sedative drugs such as morphine,* cannabis indica, or bromide of potassium; the use of cocaine and arsenic has also been suggested, but some cases prove rebellious to all remedial treatment. *Robert Saundby.*

BUNION.—(See HALLUX VALGUS.)

BURNS AND SCALDS.—When a large area of the body is involved, burns and scalds give rise to many complications, and they are injuries which it is difficult to treat satisfactorily. In the early stages profound shock and great bodily depression must be combated; indeed, the mortality following burns is greatest during the first twenty-four hours which follow the injury. This shock must receive appropriate treatment, saline injections being most valuable, and at the same time every effort must be made to prevent any further loss of vitality through prolonged exposure and manipulation. In any case of extensive burns there is a danger of asphyxia. It is necessary to bear these dangers in mind, for prompt performance of artificial respiration, together with oxygen inhalations, may be most effective in meeting these complications. Subsequently there is considerable risk of septic absorption from the large sloughing surface, and fatal issues are due to the development of low forms of pneumonia, duodenal ulceration, and meningeal inflammation and thrombosis. In the final stages much trouble will be experienced in dealing with large granulating surfaces and with rapidly contracting scars—scars which, if left, may cause permanent deformity and disablement.

* Morphine should not be used for fear of inducing the habit.—AMERICAN EDITOR.

TREATMENT.—The treatment then, will be considered according to three main stages : (1) Immediately after infliction ; (2) During separation of the sloughs when repair is taking place ; (3) When granulations have appeared and the wound is beginning to cicatrize.

1. *Immediate Treatment*.—The patient must be put to bed as soon as possible, the clothes must be cut off, and without delay or exposure a dressing must be applied over the whole of the damaged area. If the burn is very extensive, it is better to deal gradually with different regions than to completely strip and expose the whole surface at once. Charred skin or dead tissues should be snipped away carefully with scissors, if this step can be accomplished quickly. Blisters should be cut open, so that the serum can drain away. If the clothes adhere, and if there is a large amount of dirt present, it is advisable either to immerse the part in a warm (100° F.) boracic acid bath, or to soak it with warm boracic acid solution.

A number of different applications have been recommended after the above preliminaries :—

a. *Oily dressings*, which have little tendency to adhere to the burnt surface—eucalyptus oil and vaseline, or the ointment of Réclus :—

R Phenazoni	3j	Phenol	gr xv
Salol		Hydrargyri Perchloridi	gr ij
Acidi Borici	āā 3ss	Vasellini Puri	3 vii
Iodoformi	gr xv		

This can be diluted by the addition of more vaseline if necessary.

b. *Antiseptic dressings*, which may be left unchanged for some time. Lint soaked in a saturated solution of picric acid is applied to the part, and over this layers of cotton wool are secured by a bandage. As an alternative, an antiseptic cyanide gauze dressing may be used.

Werner's treatment consists in soaking the burnt part in a 2 to 5 per cent solution of carbolic acid, which is anæsthetic and antiseptic. The acid is removed by a second bath of normal saline solution, and the surface of the burn is dusted with a powder composed of acetanilide 1 part, zinc stearate 5 parts ; over this narrow strips of Lister's green protective are placed, and the whole region is finally covered with wet sublimate gauze, and bandaged.

Stimulants will be required until the shock has passed off ; later, iron and quinine should be given, digitalis and nux vomica if there is evidence of cardiac weakness. Morphia may be necessary, but must be given with caution.

When the part has been dressed, provided that no symptoms of septic poisoning arise, no attempt should be made to interfere with the damaged part. The dressings may be left alone for several days. But if, as is usually the case, the wound does not remain clean, the dressing must be changed repeatedly, as with any large septic wound. It is often necessary to perform this dressing under an anæsthetic, owing to the pain which it inflicts upon the patient.

2. *Treatment during the Separation of the Sloughs*.—If the burn has not remained aseptic—and it is very difficult to ensure this condition—a considerable amount of offensive discharge will accompany the separation of the dead from the living tissues. At this period, as has been said, there is great danger of complications developing from septic absorption. The separation of the sloughs should be assisted with scissors, so that very little dead tissue remains to harbour putrefactive organisms. All purulent blebs or foci should be opened up, and the dressings should be frequently changed. If the position of the part permits it, a weak antiseptic bath is most satisfactory ; this failing, large fomentations may be applied to the sloughing surfaces. In milder cases an oily dressing as above described may be continued until granulations have appeared.

If antiseptic baths or lotions are used, they must be made up very dilute, as

the large surface exposed to their action readily permits of the absorption of the poisons from which they are made, and it is no unusual thing for carbolic or mercurial poisoning to occur during the treatment of a burn.

During this stage the patient's temperature will rise, and he will exhibit signs of septic poisoning.

3. *Treatment when the Wound has begun to Granulate.*—The main objects now are to accelerate the healing process, and to prevent undue contraction. If the granulations are flabby and unhealthy, stimulating lotions—e.g., lotio rubra—should be applied, and general tonics—nux vomica and iron—should be administered. As a dressing, nothing is more satisfactory than a piece of green protective, a number of holes being cut in it to prevent the retention of the discharge. The protective is placed directly over the granulating surface, and is then covered by sterilized gauze. Under this treatment the granulations become flat and healthy, while the growing epithelium is not damaged each time the dressing is changed. The wound should be well irrigated with normal saline or boracic acid solution once or twice a day.

If large areas of granulation remain, and the epithelium is sluggish in covering them, skin grafting must be employed in order to diminish the risk of subsequent contraction.

During this stage every care must be taken to check this contraction, especially in the neighbourhood of joints. For this purpose splints should be employed which exert a force in the direction opposite to that of the adjoining fibrous tissue, and as soon as possible the scar should be massaged and stretched. Gentle kneading and stretching alone are required, or the scar will be torn open.

Scalds involving the mouth or fauces are especially dangerous in that they may produce œdema glottidis—an inflammatory exudation into the aryteno-epiglottidean folds. In all such cases the patient must be carefully watched, and if urgent dyspnoea is noticed, no time should be lost either in performing tracheotomy or in introducing an intubation tube, according to the needs of the case.

W. H. Clayton-Greene.

BURSÆ, AFFECTIONS OF.—Bursæ are sacs developed to minimize the effects of pressure and friction. Some are anatomically constant; others develop in response to pathological conditions—e.g., hallux valgus, gibbus in caries of the spine—and are called false or adventitious bursæ. As a rule, these latter do not show the unilocular character of an ordinary bursa.

INJURIES OF BURSÆ.

These are common, and may be either: (1) *Bruises*; or (2) *Penetrating wounds*.

1. **Bruises.**—These are more common in a bursa which was previously enlarged. Absorption of the hæmatoma may be very slow, the inner wall of the bursa being lined by endothelium. Under the bursa there may be some fracture of a bony prominence. It is rare for the clot to be completely absorbed, a fibrous thickening of the wall of the bursa being a common sequel. Finally, the hæmatoma may suppurate.

TREATMENT.—*a.* A radiograph should be taken—especially in a hæmatoma of the bursa over the olecranon, to exclude fracture of the ulna.

b. If there is the slightest abrasion of the skin, it must be cleaned thoroughly and protected from infection.

c. For the first twenty-four hours apply cold, either an ice-bag or an evaporating lotion.

d. Aid absorption of the clot by firm pressure, either by strapping or bandaging firmly over wool. Remember that if the elbow be bandaged, it must be

bandaged in a flexed position. The arm must be put at rest in a sling, and massage will aid the absorption.

e. If the constitutional symptoms, and œdema over the swelling, point to suppuration, the hæmatoma must be incised and drained.

2. Penetrating Wounds.

TREATMENT.—The wound must be thoroughly cleaned, painted internally and externally with either tinct. iodi mitis or a 2 per cent solution of iodine in rectified spirit, any dirt or foreign material be removed, an aseptic dressing applied, and the part kept elevated and at complete rest. If suppuration takes place, there is danger of the underlying bone becoming infected; or, secondly, of the discharge of pus being followed by a serous discharge from the wall of the sac. The only treatment for this latter is excision of the bursa.

INFLAMMATION OF BURSÆ.

This is either (1) *Acute*; or (2) *Chronic*.

1. **Acute.**—This may be due to injury or sepsis, the sepsis gaining an entry from a penetrating wound, or being conveyed to the bursa by the lymphatic or blood system.

TREATMENT.—If we are certain that the exudation is serous, the part must be put at rest on a splint and elevated, and either cold applications to reduce the inflammation, or fomentations to ease the pain, must be applied locally. If pus be suspected or diagnosed, the bursa should at once be opened by free incision, the part fixed on a splint, and hot fomentations applied. Should the infection, say of an olecranon or prepatellar bursa, have come from a septic place on the hand or foot, the primary sore must be dealt with at the same time.

2. **Chronic.**—This is due to either: (a) Trauma; (b) Tubercle; or (c) Syphilis.

a. *Traumatic Chronic Bursitis.*—The most familiar examples are housemaid's knee and miner's elbow. Treatment is necessary if:—

i. The enlargement is disabling.

ii. The patient complains of weakness or aching in association with a deep-seated bursa.

iii. There is any evidence of pressure on nerves—e.g., the psoas bursa on the anterior crural nerve, or the bicipital bursa on the median.

TREATMENT.—If the swelling be a recent development, it may subside with rest and change of occupation—i.e., removal of the cause of irritation—counter-irritation in the form of a blister, or repeated painting with iodine. This treatment is tedious, and is apt to fail. Aspiration and injection of the sac with carbolic (1–20) or tinct. iodi mitis (B.P.) may be tried, but is also apt to fail. The best treatment for bursitis of any standing is entire extirpation of the sac. The incision must be planned so that the patient does not press on the scar in his occupation afterwards, and should not be directly over the bursa, as the skin is apt to be thin or adherent. The operation must be done with every precaution against sepsis, the danger being infection of an underlying bone or joint. Should any part of the sac be so adherent as to defy removal, it should be scraped with a sharp spoon and painted with pure carbolic.

b. *Tuberculous Bursitis.*—This may be due to spread of infection from the underlying bone, or it may be primary. The condition is suspected in a chronic bursitis for which no explanation is forthcoming in the way of trauma, and which comes on in a young person free from syphilis.

TREATMENT.—The ordinary constitutional treatment for tubercle—open air, sunshine, cod-liver oil, and tuberculin—must be faithfully carried out. The underlying bone or joint must be x-rayed, for the best treatment of a secondarily-infected bursa is to treat the primary bony lesion. If the bursitis be primary, then the bursa must be completely excised. A tedious and difficult operation;

but the complaint is also a tedious one, and the scraping of sinuses and the opening and draining of abscesses is useless in the production of a cure. The condition is most commonly seen in one of the bursæ under the gluteus maximus in the region of the great trochanter, and the dissection is tedious, but necessary.

c. Syphilitic Bursitis.—Bursæ may become inflamed during the secondary stage; but the condition is obvious, and the treatment curative. A tertiary syphilitic bursitis is more common in the prepatella bursa than in any other site.

TREATMENT.—Potassium iodide and mercury must be given; but there are cases in which the mass of fibrous tissue seems to resist the effect of iodide, and the only treatment is excision.

AFFECTIONS OF CERTAIN SPECIAL BURSAE.

Subdeltoid Bursa.—Soon after the onset the elbow must be carried in a sling, kept at rest, and counter-irritation in the form of a blister or iodine applied over the point of the shoulder. Massage and passive movements should be commenced as soon as possible, for if the bursa become obliterated by adhesions, the result may be limitation of movement at the shoulder-joint. Should the effusion persist, the bursa must be excised by partial detachment of the deltoid from its origin. Should adhesions limit the movement of the shoulder, good results follow manipulation under an anæsthetic, with prompt massage and movement.

Bursæ in the Region of the Hip.—1. The bursa over the ischial tuberosity, when enlarged, is the cause of “weaver’s bottom”; its removal is tedious, and may involve a long dissection; but it is the only sure method of cure.

2. The bursa under the iliopsoas commonly communicates with the hip-joint when the former is found diseased. Its removal is very difficult, and endangers the nerve and vessels. In one case, the only thing I could do was to insert silk threads from the lumen of the bursa into the subcutaneous tissue, so as to form a permanent drain for the chronic enlargement of the bursa. In that one case the treatment was successful.

3. The bursa round the trochanter. This is a favourite site for tuberculous infection of the bursa. It is very apt to be mistaken for a tuberculous hip, or a tuberculous trochanter, although indeed the latter may actually be present.

Bursæ around the Knee-joint.—1. “Parson’s knee” is a chronic enlargement of the bursa over the tibial tubercle and the lower part of the ligamentum patellæ. The treatment is change of occupation, or excision.

2. At the back of the knee-joint there are six bursæ. The one that is most commonly enlarged is the one between the semimembranosus and the inner condyle of the femur and the inner head of the gastrocnemius. It forms, when distended, a rounded swelling in the popliteal space. The treatment for this enlargement is a back splint, a bandage over wool, and painting with iodine. It may take eight to ten weeks to disappear, and the treatment therefore is tedious. Excision is more rapid and more certain; but the bursa itself at times communicates with the knee-joint.

Bursa between the Tendo Achillis and the posterior surface of the Os Calcis.—When inflamed it gives rise to considerable disability, which must be treated by rest and counter-irritation.

Robert Milne.

CAISSON DISEASE (Compressed-Air Illness).—In the iron caissons employed in subaqueous and tunnelling excavations, the workmen are exposed to atmospheric pressures two to three and a half times greater than that of the ordinary atmosphere. That they may be able to work at these pressures, the men in passing into the caisson are subjected to gradual increments of pressure in the adjoining air-lock. They undergo what is known as “compression.” Men

who are beginning work for the first time often experience severe pain in the ears during compression, and become giddy. As these symptoms are due to excessive pressure upon the membrana tympani, they are averted by the workmen swallowing air and allowing it to pass up the Eustachian tube. After finishing work, the men, before returning to the outside, undergo in the air-lock "decompression." It is after emerging from the air-lock that the typical symptoms of caisson disease arise, viz., severe pains in the muscles of the limbs and trunk, known as "bends," also paralysis of the lower extremities and of the bladder, requiring the use of the catheter. Other minor symptoms, such as headache, vomiting, epistaxis, hæmoptysis, and restlessness, usually disappear with rest in bed. For the muscular pains, a hypodermic injection of morphia is often required. Since the more serious symptoms depend upon the sudden disengagement in the blood and tissues of the nitrogen which has been inhaled in the atmospheric air, or, in other words, upon frothing of the blood owing to a rapid fall of pressure, experience has shown that the most successful treatment is to place the men back again in the air-lock, to compress them slowly, and then very gradually to decompress them. Plenty of time should be spent in the act of decompression—five minutes to each atmosphere being a fair average. Decompression by stages, i.e., rapid decompression from a high to a lower pressure and then stoppage for a few minutes, followed by a series of further reductions and stoppages, has been recommended, but a larger experience is required to show its superiority over slow and gradual decompression.

Thomas Oliver.

CALCULUS.—(See also URIC ACID GRAVEL.)

Vesical Calculus.—

The detection of stone in the bladder is compassed by several methods. The bladder sound will, in the majority of cases, enable the practitioner to ascertain the presence of calculus, but in some instances the sound, even in the most skilled hands, will fail to detect its presence. When the prostate has a very large intravesical projection, stones are often found lying in a deep post-prostatic pouch. In some cases stones are formed in sacculations, and it must be remembered that a sacculus of the bladder is sometimes larger than the true bladder cavity, and may have an opening not large enough to admit the index finger. In the first instance the sound cannot possibly feel the stone, and in the second good luck rather than good management would alone guide the sound into the sacculus. These two instances are sufficient to show that further methods of diagnosis are essential in cases where symptoms of stone exist and the sound fails to detect its presence.

The writer advises two methods: (1) Suction with the litholapaxy evacuator; (2) Cystoscopy. The former can be applied by any practitioner; the latter requires considerable practice to be of serious value.

In the former method four or five ounces of sterile water are injected into the bladder through a No. 10 or No. 12 litholapaxy catheter, and the rubber evacuator bottle filled with water is then applied. When the bulb of the evacuator bottle is squeezed and released, fluid is first made to swirl around inside the bladder, and will often dislodge a stone from beneath the prostate or from some wide-mouthed sacculus, and when the bulb is released the fluid is sucked back sharply into the bottle, and will bring the calculus up against the eye of the catheter with an unmistakable sharp click.

Cystoscopy of course reveals every part of the bladder, but should be reserved for expert hands, as the writer has seen surgeons who have had little experience with the instrument mistake phosphate-covered malignant growths for stone on the one hand, and stone covered with shaggy muco-pus for growth on the other!

TREATMENT.—The operative treatment of vesical calculus has been revolutionized by the gradual perfecting of lithotripsy with the removal of the fragments at one sitting, to which the name of litholapaxy is now applied. The death-rate is very low when improper cases are excluded and the operation is placed in skilled hands. The following table from the reports of St. Peter's Hospital, London, will show the marked improvement which has resulted :—

DECADE	OPERATED UPON BY LITHOLAPAXY	DEATH-RATE
1864-73	118	15.25 per cent.
1874-83	196	15.30 "
1884-93	362	8.29 "
1894-1903	600	4.83 "
1904-1913	578	3.28 "

It is justifiable to state with assurance that litholapaxy is the operation of choice for the treatment of vesical calculus, but certain cases must be dealt with by lithotomy, either suprapubic or perineal. Where the operator has had no opportunities for acquiring skill with the lithotrite, the safest operation is probably suprapubic lithotomy. The advantages of the crushing over the cutting operation are obvious. The stay in bed and in hospital is short—in an uncomplicated case the patient should be out of bed in forty-eight hours and fit to leave the hospital in three or four days; there is practically no loss of blood; and there is no scar, as in the case of suprapubic lithotomy, and consequently no distortion of the bladder.

The cases in which lithotomy should be substituted for litholapaxy are :—

1. In very young infants. Children above the age of four do very well with litholapaxy, provided great gentleness and skill with the instruments can be obtained. In performing litholapaxy in children the stone must be crushed to fine dust, as only very small evacuators can be used. No force whatever must be exerted to pass either the lithotrite or the evacuating cannula, and the evacuation of the fragments must be done gently, very little force being used in squeezing the bulb of the evacuator.

2. Stone complicated by very severe cystitis should be treated by lithotomy, so as to secure adequate drainage of the septic bladder, unless prior to operation the cystitis can be cleared up by rest in bed and irrigation.

3. Sacculaton of the bladder complicating stone should, if of considerable extent, direct the surgeon's choice to suprapubic lithotomy rather than litholapaxy.

4. If the stone or stones are actually in a sacculus, the difficulty of picking them out with a lithotrite and then crushing them is great if the sacculus is a shallow, wide-mouthed one, and insurmountable if the sacculus is deep and with a small aperture.

5. If a large smooth stone is in a bladder which is much sacculated, but is not actually in a sacculus, lithotomy should be done rather than crushing, for although the stone can be easily caught and crushed, sharp fragments are liable to fall into and be retained in a sacculus, setting up ulcerative changes which finally lead to perforation and extravasation. The advisability of detecting this condition of sacculaton before operating by litholapaxy upon stones which are apparently quite freely movable in the bladder has led the writer to cystoscope all cases of vesical calculus before determining upon the nature of the operation to be performed.

Considerable enlargement of the prostate is not a bar to litholapaxy in skilled hands, but it increases the difficulty of the operation very materially, and the proper treatment, where the patient's consent can be gained, is to remove the calculi by a suprapubic cystotomy, and proceed to a prostatectomy upon the same occasion if the patient's condition warrants it, or after a week or ten days' drainage of the bladder if that viscus is very foul and septic when the lithotomy is done. Stricture of the urethra, unless thoroughly dilated or cut, is an absolute bar to litholapaxy, for the first essential to the success of that operation is that the lithotrite should move easily and freely in the passage.

With regard to the size of the calculus and its composition, it may be said that the more skilful the lithotritist the larger is the stone that can be dealt with by

litholapaxy. There is one variety of calculus, fortunately a very rare one, which if large should always be removed by cystotomy, viz., the cystin calculus. This material is so tough that the blades of the lithotrite have but little effect upon it if the stone is large. Usually the nature of the case is recognized only after an attempt has been made to crush the stone. It is wise to change the method in mid-attack, and substitute a suprapubic lithotomy for the litholapaxy.

Perineal lithotomy, either lateral or median, is but rarely seen now in this country. It is practically only required when perineal drainage is desired after the removal of the stone. It possesses no advantages over suprapubic lithotomy except that the patient can be got out of bed somewhat sooner. For the removal of very large calculi from contracted bladders, suprapubic cystotomy should be employed rather than litholapaxy or perineal lithotomy.

Ureteric Calculus.—Calculi which have left the kidney may be met with in any part of the ureter, but they are particularly liable to be arrested in three situations: (1) Just at the exit from the renal pelvis; (2) At or just below the spot where the ureter crosses the iliac vessels; and (3) At the entrance of the ureter into the bladder. The diagnosis of ureteric calculus is made from the symptoms, the physical signs, physical examination, and by the employment of radiography, cystoscopy, and ureteric catheterization.

TREATMENT.—When the ureteric stone is small, and in the lower end of the ureter, it may sometimes be coaxed into the bladder by finger pressure, through the rectum in the male and through the vagina in the female. If this fails it may be removed through the ureteric papilla by a suprapubic cystotomy in the male, and by an incision into the vault of the vagina in the female.

Below the brim of the pelvis, stones may be extracted from the ureter by an intra- or extra-peritoneal operation. Wherever possible the extraperitoneal operation should be chosen. The intraperitoneal is more properly a transperitoneal operation, for the ureter, of course, lies extraperitoneally throughout its entire course, and in this operation the parietal peritoneum must be incised both on the anterior and posterior walls of the abdomen. Access is gained to this portion of the ureter extraperitoneally through an incision similar to that used for the extraperitoneal ligature of the iliac vessels. The peritoneum is stripped up from the sides of the false and true pelvis, and it must be remembered that the ureter goes with (but outside) the peritoneum, and will be found adherent to it.

Calculi arrested in the ureter anywhere above the brim of the pelvis should be approached by an extraperitoneal incision. Morris's lumbo-ilio-inguinal incision, which commences in the loin in front of the transverse process of the last lumbar vertebra, and runs parallel with the curve of the crest of the ilium forwards, gives an exposure which allows the kidney and practically the whole length of the ureter to be explored.

In a few cases the stone is arrested just outside the bladder. It is then difficult of approach by the iliac route, and too far up the ureter to be extracted through the ureteric papilla by means of a suprapubic cystotomy. In these cases the parasacral route has been employed, the lower end of the ureter being approached by an incision parallel to the sacrum, the rectum being displaced to one side or the other. The operation is exceedingly difficult and tedious, as the ureter lies at a great depth from the surface.

Calculous Anuria is the most serious complication of ureteric and renal calculi. This condition occurs usually when one kidney has for some time been doing the whole work, owing to the destruction of the opposite kidney by disease, or after its removal by operation. Calculous anuria does not always depend upon complete obstruction of the ureter by an impacted calculus, although in our opinion

the term should be restricted to such cases. Suppression occurs sometimes after the removal of stones from one kidney, the other kidney also being full of stones. The shock of the nephrolithotomy is sufficient to induce suppression although neither ureter is blocked, and to this suppression the term calculous is sometimes applied. Very rarely both ureters may become blocked with calculi almost simultaneously, but usually by careful investigation of the history and symptoms it will be found that there is a longer history of symptoms upon the one side than the other.

If the patient is in good condition, and the situation of the ureteric stone can be determined, an immediate operation for its removal should be undertaken upon the lines already mentioned. If the stone cannot be localized, a nephrotomy should be done upon the side where the symptoms last appeared, for it is probable that the kidney in which the symptoms are of long duration is destroyed and functionless. Once the diagnosis is established, operation—either nephrotomy or ureterolithotomy—should be done at once; for if the anuria is allowed to persist for any length of time the kidney will not secrete again. If a palliative nephrotomy succeeds in restoring the flow of urine, it should be followed, when the patient has sufficiently recovered, by a careful exploration for the obstructing stone.

When the anuria is not of the obstructive type, nephrotomy is the right course to pursue, with immediate removal of the stones from the kidney if the patient's condition is sufficiently good, or at a later period if this is deemed wiser.

Renal Calculus.—Renal calculi vary from fine gravel to huge masses of stone completely filling and disorganizing the kidney. Cases of gravel are usually of two types, the alkaline and the acid diathesis accounting for the difference, and it should be remembered that even when no definite calculi are formed, all the symptoms of renal stone may be caused by these conditions, lumbar pain, hæmaturia, and indeed true attacks of renal colic occurring in patients suffering from phosphaturia on the one hand or uric acid storms upon the other. In the treatment of these minor calculous conditions, drugs, diet, hygiene, and the use of natural waters must be relied upon. Phosphaturia usually depends upon over-work and mental anxiety, and varies from the passage of a small amount of phosphates in the urine, accompanied by backache, lassitude, and general weariness, to the excretion of huge quantities of phosphates, coagulated sometimes into small calculi, and accompanied by severe attacks of renal pain, hæmaturia, and very often urgency and frequency of micturition, the latter due to the extremely irritating effect of the phosphate-laden urine upon the vesical and urethral mucous membrane.

TREATMENT.—This consists in giving, if possible, an entire change of life and scene. The over-driven brain-worker should have plenty of reasonable physical exercise in congenial and pleasant surroundings; a change to the sea-side is often most beneficial. The diet should be the fullest and most nourishing that the patient can digest, and alcohol in small quantities has very often a beneficial effect. By drugs the urine can almost always be cleared of phosphates for a time. The writer has found the following prescription of great value in these cases:—

R Hexamethylenaminæ	gr x	Acidi Nitrohydrochlorici Diluti	℥x
Sodii Phosphatis Acidi	gr xx-xxx	Infusi Gentianæ Co. (N.F.)	q.s. ad ʒj

Three times a day, after meals.

Hexamethylenamine combined with dilute mineral acids and bitters seems to exercise an almost specific effect upon phosphaturia. When, however, it is very obstinate, a visit may profitably be made to one of the mineral water establishments; the best of these is Bad Wildungen, near Frankfort. A "cure" at this spa, lasting from a month to six weeks, frequently completely clears up a case

which diet, drugs, and careful hygiene at home have failed to influence markedly. The treatment of uric acid gravel, on the other hand, proceeds upon exactly opposite lines. A diet practically deprived of flesh, prohibition of alcohol, and the exhibition of alkalies and vegetable acids, are indicated. The waters of Vichy, Contrexéville, and Aix-les-Bains are deservedly popular in these cases, owing to their success. In the writer's opinion the best mineral water for this condition is undoubtedly that of Contrexéville. It is claimed by those who have large experience that it not only induces a very free diuresis, thus diluting the usually concentrated urine of these patients, but that it possesses a specific action upon the musculature of the ureter, and so increases ureteric peristalsis. However well founded this belief may be, there is no doubt that a course of the waters at Contrexéville is often efficacious in causing the discharge of immense quantities of uric acid in the form of red gravel, the so-called cayenne-pepper gravel, and in many instances, of quantities of small calculi.

Operative Treatment.—The surgeon has the choice of removing the stones from the kidney, or the kidney and the stones together : nephrolithotomy or nephrectomy. Nephrolithotomy is unquestionably the operation of choice, for, although a human being can exist with only about two-thirds of one kidney, the surgeon should always make every attempt to save as much kidney substance as possible. When the kidney is full of stone and is suppurating in all directions, immediate nephrectomy is of course advisable, but in all cases where there seems the least chance of saving the kidney, nephrolithotomy should be first performed, and be followed by a nephrectomy at a later date if the kidney obstinately refuses to heal.

Operation in cases of renal calculus is called for firstly to save the kidney, and secondly to save the patient's life. In this connection the practitioner should remember that stones may form and remain in kidneys, causing very slight symptoms, through the whole of life. A small fixed stone in the renal cortex, provided no bacterial infection occurs, may exist with absolutely no symptoms, and such stones are not infrequently found in post-mortem examinations of patients who have never complained of symptoms referable to their presence. Such stones too may occasionally cause modified attacks of discomfort, pain, and transient hæmaturia and albuminuria. In such cases it is not essential to urge operation upon the patient, but when repeated and disabling attacks of pain and colic occur, together with evidences of renal destruction such as continued hæmaturia, albuminuria, and especially pyuria, it is the practitioner's duty to urge immediate exploration.

With regard to the technique of nephrolithotomy, the writer would urge the advisability of removing stones through an incision in the pelvis rather than the cortex of the kidney, whenever this is feasible. A vertical incision in the pelvis can be continued into the cortex at right angles to the long axis of the kidney if more room is required. This incision, running in the same direction as the renal vessels, is preferable to the incision along the convex border of the kidney, as it leaves far less cicatrization and consequent impairment of the functions of the kidney.

John George Pardoe.

CANCER.—(See under respective regions.)

CANCER, GENERAL TREATMENT OF PATIENTS SUFFERING FROM.—

In this short article no reference is made to treatment by operation, or by such specific means as *gamma* radiations or drugs stated to be able to modify directly the course of malignant disease. It deals only with the measures that appear to the writer to promote the comfort and well-being of patients suffering from this malady. Let it not be thought that these measures, although general, are unimportant. One often hears it said by the public that "the doctors have

told so-and-so that they can do nothing more for him," because he has inoperable cancer. This is never true! Proper care can always help these patients, and do much to prolong life and lessen the distress caused by the disease. It is a striking fact that all the patients with advanced cancer who are admitted to the Middlesex Hospital Cancer Charity improve, at any rate for a time.

1. Rest.—It is very important that patients suffering from cancer should be spared all fatigue. It is well for many of these patients to continue at their usual work, but only while able to do so without getting tired. The heavy housework that many women are engaged in is very injurious to those suffering from cancer, and relieving them of it always has a marked beneficial effect. But these patients need not only to avoid general fatigue; they should particularly keep the diseased organ at rest as far as possible. A man with cancer of the tongue should talk as little as he can, and the taking of food should be rendered as simple and easy for him as possible. In cancer of the pharynx or gullet, food that is swallowed *easily* should be taken in preference to food that can only be swallowed with an effort; and in cancer of the rectum, the motions should be as far as possible reduced in bulk and softened in consistency, so that they may be passed easily through the narrowed bowel. The good effect of such palliative operations as tracheotomy, gastrostomy, and colostomy is certainly in part due to the local rest they secure.

Almost as important as general and local physical rest is mental rest. Worry is a bad bed-fellow under all conditions, but in none is it more injurious than in the subjects of advanced cancer. It is quite easy to get evidence of this. Part of the improvement that results from the admission of poor men and women into well-appointed cancer homes and wards is due to the mental rest they thus secure. If for any reason this mental rest is broken in upon, as by bad news from home, the misbehaviour of some member of their family, or the sudden death of a patient in the same ward, it is quite common to see the result in physical ill-consequences such as increased pain and discharge, sleeplessness, rise of temperature, and even increase in a growth or aggravation of ulceration and sloughing. Again, it is striking to see how "kindly" the progress of the disease often is in placid, cheerful subjects, while it is always worse in those of irritable, fretful, and gloomy dispositions. Of course, these conditions have also the reverse relationship. Increased dyspnœa and dysphagia will induce grave anxiety, severe hæmorrhage and pain will depress mentally as well as physically. But after freely admitting all this, the observation, now extended over many years, of cases of cancer in their later stages has convinced me that the other side is still more true, and that mental "worry" has a distinctly injurious effect upon the course of the disease. Nothing is more remarkable than the power many women and some men have of maintaining a placid mind, and even a cheerful temper, through what to those around them is a long and distressing illness.

2. Cleanliness.—It would be difficult to exaggerate the importance of securing cleanliness in cases of cancer. It is only equalled by the difficulty in obtaining it in some of the cases.

General cleanliness of the body is valuable, and the services of a good nurse who will not neglect this part of her duty, even to the end of the case, and, it may be, in opposition to the wish of her patient, are invaluable. But it is to the value of local cleanliness that I wish to draw particular attention. For example, in cases of cancer of the mouth, every care should be taken to keep the teeth clean, to deal with pyorrhœa—which is often present—to remove discharge and particles of unswallowed food, and to get away sloughs. All manipulations must be gentle, and the very frequent and thorough use of cleansing lotions such as Sanitas and water, or weak solution of permanganate of potash, will be the chief means employed. But special attention should be paid to the teeth; and

where a brush can no longer be used, each tooth should be carefully cleansed with a small dossil of wool. The mouth should always be well irrigated before and after taking any food. Loose teeth should be extracted.

In cancer of the uterus, the frequent use of carefully given vaginal douches is of great value. The fluid used should be at a temperature of 105° to 110° F., feeling to the patient definitely warm. It may be of Sanitas and water, or a weak solution of cyllin in water (3ss to a pint), or of lysol or chinosol. Formalin is sometimes used; when strong enough to be effective it is apt to be very painful. When there is hæmorrhage, the fluid should be as hot as the patient can bear—about 120° F. The douche should always be given through a soft rubber nozzle, and in a gentle stream. Where a fistulous communication has formed with the rectum or bladder, every care must be taken to keep the parts clean by frequent douches and the use of pads of absorbent material such as compressed moss or peat.

In cancer of the rectum, comfort is given by gently washing out the rectum once or twice a day. When there is colostomy, the bowel below this should always be kept as clean as possible, and whenever practicable one of the lotions mentioned above should be run through the bowel from the colostomy opening to the anus at least twice a day. This greatly promotes the patient's comfort.

In external cancer, the surface should be kept as clean as possible, sloughs should be removed, discharge washed or wiped away, and the part carefully dressed. In some cases an ointment, e.g. lanocyllin, is best; in others, a wet dressing or hot fomentation is more comfortable. The application should be unirritating, antiseptic, and as a rule, deodorant. Sanitas, peroxide of hydrogen, cyllin, lysol, weak carbolic lotion, iodoform, iodine, vaseline, all have their uses.

3. **Diet.**—The diet should be an ordinary mixed diet; I have not seen any advantage from excluding either animal food, vegetables, or fruit. I would not exclude any ordinary article of diet, provided it is properly prepared and known to have suited the individual previously. I believe it to be advantageous to have mixed diet. Thus, in cases where gastrostomy has been performed, and the patient is fed through a tube, it is well to have a large tube such as a No. 18 catheter, and to encourage the patient to take not only milk and egg, but thickened soups, pounded meat, and any farinaceous foods or sieved vegetables and fruits that can pass through the tube. But while a mixed diet is of advantage, there is no good to be gained by overfeeding patients who have cancer; in the late stages especially, they are usually more comfortable with quite small meals.

4. **Alcohol.**—Alcohol has a distinct influence upon the incidence of cancer, and it is equally injurious upon its course. A free use of alcohol markedly increases the rapidity of the progress and the pain, hæmorrhage, and discharge attending a malignant growth, and it shortens the life of its victim. The entire withholding of alcohol is to be recommended; the patients are more comfortable, and the course of the disease is in all ways less distressing if none is taken.

5. **Constipation.**—It is very important to secure the regular action of the bowels of all patients suffering from cancer. Constipation adds to pain and to restlessness. On the other hand, strong purgatives are to be avoided; a sufficient motion every day—or at least every other day—is the desideratum, and this should be secured by the simplest and blandest means. Care in diet, and the inclusion of sufficient vegetables and fruit, often suffices; but very often laxatives or a daily enema are also needed. It is well worth while to take trouble to find the drug and the exact dose of it which secures the desired end without painful or excessive action.

6. **The Relief of Pain.**—It is sometimes said that the free use of morphia is the great indication in the treatment of inoperable cancer. Such a statement

is the reverse of the truth. If possible, morphia should not be used at all, and its use should always be carefully restricted and kept within the narrowest limits. If not, it may cause more suffering than the disease itself. In the Middlesex Hospital Cancer Charity, where there are always between 90 and 100 patients suffering from cancer in its later stages, morphia is now used very much less than formerly; a hypodermic injection has become an infrequent occurrence; months often elapse without one being given in a ward of 32 patients. A small dose of nepenthe or of the solution of morphia, or a small suppository of morphia, is sometimes necessary, but reliance for the relief of pain is chiefly placed upon such drugs as phenacetin and acetyl-salicylic-acid. Care in carrying out the treatment already mentioned has greatly lessened the pain that needs to be relieved. It is important to remember that the pain in cases of cancer is notably lessened in the latest stages of the disease as a rule; and as all anodynes are to some extent injurious, their use must not become a mere routine, but they must be taken when actually necessary for the relief of present pain. We are often able to suspend their use altogether.

Other measures to relieve pain are local heat, x rays, radium, and the division of sensory nerves. The division of the posterior spinal nerve roots is justifiable where pain is extreme and the sensation is conveyed along a limited number of nerve roots.

7. Hæmorrhage.—This is a frequent incident in cancer. It is often prevented by the use of radium, especially in cancer of the uterus or of the rectum. It is to be generally dealt with by strict rest, the gentle use of douches as hot as can be borne, and in some cases a styptic may be added to the fluid. In external cancer, a cavity can be plugged, or a bleeding point treated with a pledget of wool on which is some powdered dry sulphate of iron, which is gently pressed upon the spot and left adherent to it. Operations to arrest hæmorrhage or to relieve the consequent anæmia should not be performed in cases of inoperable cancer.

Colostomy, performed for other reasons, often does further good in lessening the hæmorrhage from a very vascular and bleeding cancerous growth in the rectum.

8. Sunshine.—Patients with cancer should of course be nursed in very well ventilated rooms, and care should be taken to keep the room as bright and sunny as possible, e.g., a room with a southern aspect should be chosen, heavy curtains and blinds should be dispensed with, and the patient's bed or chair be placed near the widely opened window. Whenever feasible, patients should spend as much of their time as possible resting out of doors in the sun—not under the shade of trees or under balconies. I think that the value of out-of-doors treatment is not due solely to the "fresh air," but quite as much, if not more so, to the value of direct sunlight. At any rate, I think I have seen so much advantage from it that I am justified in laying stress upon the importance of this point.

9. Mental and Moral Atmosphere.—The last point I would refer to is the importance of keeping the patient in a bright mental and moral atmosphere. As far as possible conversation should be on other subjects than the illness and its details. Depressing visitors and books should be forbidden, cheerful companions are most helpful, and pains should be taken to make all the surroundings of the patient as bright and cheerful as possible. And this raises the point of whether we should let the patients know the nature of their ailment, and the gravity of the prognosis. The writer is convinced that far too much stress is laid upon the importance of concealing these facts from patients. He has not seen any distressing results from frank but kindly-phrased answers to questions. On the other hand, he has known much additional distress arise from unnecessary concealment and deception, and in some cases quite serious and unnecessary complication in the management of the case caused by it. It

is not the surgeon's duty to volunteer information of the nature and course of the case, nor to tell his patient the details of possible future developments; but it is equally not his duty to deceive his patient, and he need have no fear of the consequences of kindly, truthful answers to questions. In no case, however, should he venture to state how long a patient with cancer is likely to live. He does not know, and it is never wise to try to lift this veil.

Alfred Pearce Gould.

CANCERUM ORIS.—(See STOMATITIS.)

CARBONIC ACID SNOW, TREATMENT BY.—Solid carbon dioxide was first introduced into therapeutics by Pusey, of Chicago, in 1907, and most of those who have had a large experience in its use will agree that it is one of the most remarkably successful therapeutic agents of recent years.

Its advantages over other freezing methods are both numerous and striking. It is plentiful, cheap, and easily obtained; the preparation of the solid crayon is not difficult, it can be moulded, shaped, or cut to any desired form, and its temperature remains constant. This, while low enough for our purpose, is not so low as that of liquid air, so that its action is under the most perfect control. The application is attended with so little pain or discomfort that no anæsthetic, either local or general, is ever necessary. In any case the application is a matter of seconds only, while the time between the application and the reaction is a matter of minutes. A blister often follows, and after this a crust forms, which is allowed to come off in its own time—a week or ten days after the application.

Not the least of the properties of this substance is its very high efficiency. Success is the rule, failure being almost always due to faulty technique or to its use in unsuitable cases.

Preparation.—Many different forms of apparatus for the easy and rapid preparation of the snow are now to be obtained from most instrument makers, and as full instructions are always sent there is no need to give further details here. The main requirement is a cylinder of the compressed and liquefied gas. Owing to its extensive use in the aerated water and other industries, these cylinders are very easily obtained and are quite inexpensive.

The pressure inside the gas cylinders is about forty atmospheres. They are provided with a valve that can be controlled by the hand quite easily. When the liquid is allowed to escape through the small opening made by giving the valve a slight turn, rapid expansion and evaporation take place, with the result that intense cold is produced and a certain portion of the escaping liquid becomes frozen into a semi-solid, like ordinary snow.

The cylinder, when obtained, is mounted on a stand at a convenient height, so arranged that the valve end is some inches lower than the other. This ensures that the liquid lies over the inner side of the valve. The cap screwed over the outlet is removed with a spanner, and a short nozzle screwed on in place of it. If a chamois leather bag be held over the opening while the valve is opened the snow is collected, and may then be moulded into a crayon by compressing it in a short length of metal tubing; this latter may be of any convenient size or shape. This simple method may be adopted if more elaborate apparatus is not available. Owing to the rapid evaporation of the crayon, it frees itself from the inside of the tube in a few seconds, and is easily pushed out. A turn or two of lint is wrapped around it and it is ready for use. In this state it can be cut with an ordinary knife, or shaped by pressing it against any metallic mass, to suit the requirements of any case we may wish to treat.

The snow returns to the gaseous form fairly rapidly, without an intermediate

liquid stage. It is this evaporation which keeps the crayon at its low temperature, and makes it possible to hold a piece loosely in the hand without injury; it floats on a cushion of its own gas, and is really never in actual contact with the skin under such conditions. The return to the gaseous form is not so rapid as to cause inconvenience: a crayon one inch in diameter, freely exposed in an ordinary room, will last for from one to two hours, and much longer if wrapped in cotton-wool or placed in a Thermos flask, the mouth of which is to be stopped with cotton-wool and not corked.

Lately the use of this snow with ether has been revived. We experimented with this in 1909, but as it did not appear to have any special advantages its use was not continued. If a solid crayon is immersed in ether, it becomes softer, more translucent, and the temperature is lowered to some extent. The lowering of temperature is not sufficient to compensate for the loss of solidity. If, however, the soft snow is added to a small quantity of ether, after a little preliminary ebullition it appears to dissolve in the latter, and a colourless semi-gelatinous "solution" is formed. It may in fact be looked upon as a mild substitute for liquid air. It can be applied with a brush or swab, and has been found useful for some superficial conditions, and also for application to the mouth, nose, and other cavities.

Mode of Application.—This is very simple, but to get uniformly good results a certain amount of practice and experience is necessary. The difficulties are very much reduced by the fact that the temperature of the crayon is always a constant one, viz., -79°C . (-110°F). If its temperature rises ever so little above this it becomes gaseous. Thus the surface of the crayon is being constantly renewed.

The crayon is held in the hand with a small piece of lint, and after the end has been shaped to the part to be treated it is pressed against the latter firmly for a period of from ten to sixty seconds, or even more in special circumstances. The degree of pressure to be employed depends upon the depth of the reaction required; but in dealing with nævi and vascular growths generally, the pressure should be sufficient to arrest the circulation. If this is not efficiently done the result is not satisfactory. Practical experience in the treatment of a few dozen cases will teach one what cannot be learnt in any other way.

Effects of the Application.—It will be most satisfactory to describe what takes place when an average case of capillary nævus is treated by this method. The crayon, having been suitably prepared and shaped to fit the growth as accurately as possible, is pressed down on to the nævus firmly for from thirty to forty seconds, according to the thickness. On the crayon being removed, the depression made by it remains, and the depressed part is white and hard, like a piece of china. The part returns to its normal contour in from two to three times the duration of the application, and when the thawing is complete the surface is seen to be covered with the moisture of condensation.

The reaction sets in almost immediately, and within a few minutes the part is of a firmer consistency than normal, and is beginning to swell. A wheal quickly forms which is well developed within an hour. Vesication almost always follows an application lasting twenty or more seconds. When a vesicle forms, it should be relieved with a sterile needle and dressed with an antiseptic ointment. Very small patches may be sealed over with cyanide gauze and collodion. A crust forms in about four or five days, and this should be left to come off of its own accord. After a properly made application of solid carbon dioxide there is no necrosis or sloughing; an intense reaction is set up, in the course of which the abnormal or diseased cells are removed.

The intensity of the reaction following an application depends upon the time the crayon has been in contact and, to a less extent, upon the degree of

pressure. With the proper manipulation of these two factors we are in a position to set up any degree of reaction we may wish, from a mild and transient hyperæmia to a complete necrosis.

A second freezing, immediately following the first, intensifies the effect considerably, and if done the following day, has an even more pronounced effect. This is of value in dealing with fleshy moles and the "port-wine stain," which remain the most unsatisfactory forms of nævus to deal with.

Indications.—The conditions in which this agent is of use are very numerous, and of special interest to dermatologists. Speaking generally, localized lesions of the skin are the peculiar province of solid carbon dioxide, whether they be new growths or disease. It is specially applicable to the treatment of nævi where these do not extend too deeply, and where the circulation is not too free, as in the cirroid aneurysm.

The great majority of *capillary nævi* may be completely removed by a single application of about forty seconds' duration, with firm pressure. Owing to the weak and fragile nature of the tissue making up this form of nævus, the top of the growth nearly always sloughs off. This, however, is no disadvantage, as the result is better than can be obtained in any other way. If the outer covering of the nævus consists of ever so little sound skin, this is not destroyed if the application is properly timed. In most cases the result is a pleasing, soft, and elastic scar, closely resembling the surrounding skin.

Cavernous nævi are not so favourable for this or any other treatment, but the great majority can be dealt with successfully. The pressure must be very firm, and where possible it should be made against an underlying bone. Also full time must be given so that the freezing may reach to the lowest part of the growth. If there should be a covering of skin, this is destroyed sometimes, but not as a rule, though the reaction has to be severe.

Port-wine marks are the most troublesome variety of nævus to deal with, probably owing to the fact that they are made up of an overgrowth of normal tissue elements, and as such are very difficult to destroy. In spite of this, solid carbon dioxide gives as good results on the whole as any other method, besides having advantages of its own. The vessels being quite superficial, in most cases no great amount of pressure is required, and an application of about thirty seconds is sufficient. The first application to any given area has very little effect in taking out the colour, but with the subsequent applications the difference is very noticeable. We must always take care to do as little destruction as possible on each occasion, so as to avoid the appearance of a scar. A course of treatment is of necessity very prolonged, but it gives rise to little inconvenience, and is always worth doing. This is an instance where the snow "solution" in ether may be substituted for the solid crayon. Only a very superficial reaction is required in most cases, and the lower temperature of the solution is an advantage.

Moles are, as a rule, very resistant, consisting as they do of an overgrowth of normal cells. They can always be removed, however, by this method, with a minimum amount of inconvenience, though some of the fleshy moles require four or five applications before the surface is level with the surrounding skin. The hairy pigmented mole is better treated by electrolytic epilation.

Common warts and corns can be removed very successfully. The crayon is trimmed down to the size of the wart, and the application is continued until a narrow zone of normal tissue around the base is frozen also. The conducting properties of this form of growth are so poor, that in treating a thick and dry wart the application may have to be as long as five minutes, and even more in some cases. In the reaction that follows the whole wart is lifted off bodily, and does not tend to recur.

One of the latest of the many successful applications of solid carbon dioxide is in the treatment of *rodent ulcer*. So far as our experience goes, it seems safe to assert that any simple case of this disease that does not involve bony structures can be cured by a single application. There has been no failure so far, though the number of cases treated is necessarily limited. The surface of the ulcer must be first cleaned off with a sharp spoon; this, if done gently, causes very little discomfort. The slight bleeding that follows is arrested by pressure with a pad of absorbent cotton. The crayon is made the shape of the ulcer, but slightly larger, and firmly pressed on the latter for about forty seconds. After thawing, the place is dressed in the usual way with an antiseptic ointment. Healing is generally complete in three weeks' time, and after the first few days the area has all the appearances of a healthy, healing ulcer, and behaves as such until scarred over. Some cases treated three years ago show no sign of recurrence, and the scars are all that could be desired. This is a very important gain to the therapeutics of this disease. Compared with other methods, it is the cheapest and quickest, and, so far as our present knowledge goes, is as efficient as any of them. For cases of long standing, and especially recurrences after other forms of treatment, this method offers no special advantages.

There seems to be little doubt that freezing by this method has a definite value in *lupus vulgaris*, though, as in the case of rodent ulcer, sufficient time has not yet elapsed to judge accurately its real value. The method is essentially the same as for rodent ulcer, and the subsequent care of the treated areas must be thorough in the way of antiseptics and general cleanliness. In the cases we have treated there has been little difficulty in getting the patches to heal without showing nodules when tested with the glass spatula.

It has a good effect in *lupus erythematosus* also, but it cannot be said to be any better than other remedies for this troublesome condition. Parts that are treated by freezing generally heal well enough, but the tendency to spread is not affected thereby. It forms a very useful alternative to other applications, and is at least as good.

Patches of *chronic eczema*, such as so often remain after a more general attack, can usually be removed by short applications of the snow. Ten seconds is generally long enough, and after the first sensations have passed off, in half an hour or so, it is noteworthy that the maddening irritation of the eczema ceases completely, though a brisk reaction may be set up. Here we have an instance of an artificially produced healthy reaction overpowering and removing an unhealthy one. This valuable use of carbonic acid snow is not so generally known as it deserves, and it seems to leave the skin more resistant and less susceptible to recurrence.

Urethral caruncle may be treated by this method. The growth and surrounding parts are freely painted with cocaine solution, and after waiting a few minutes, the crayon is applied to the caruncle and also to the base from which it sprang, each for a period of thirty seconds. The caruncle separates in a few days.

Small uncomplicated *internal hæmorrhoids* may be successfully treated by this method. It is not always easy to apply the crayon to the best advantage, and under these circumstances the ether solution may give better results. There is usually no pain, and frequently the patient's usual habits are not interfered with in any way.

Numerous cases of *trachoma* have also been treated, and here carbonic acid snow seems to be more efficient than copper sulphate, and is much less painful. The crayon is shaped to a semicircular form and pressed against the everted lid for from ten to twenty seconds. The sensation is of course not at all pleasant, but it is not nearly so severe as with other applications: the most

discomfort is the thawing out, but even this is not so severe as to cause complaint.

There are numerous other conditions in which this agent may be employed with a reasonable prospect of success. Owing to its recent introduction into therapeutics, any claim put forward for it must be taken with a certain reserve. As regards the treatment of nævi, however, we may say that it is the most generally useful method at our disposal, this statement being based upon an experience of about 600 cases, some of which were better dealt with by other means.

Reginald Morton.

CARBUNCLE.—The association of this condition with diabetes, albuminuria, and other debilitating conditions must always be borne in mind. Not that these states necessarily preclude the successful treatment of carbuncle by operation; indeed, in many cases there is an improvement in the glycosuria or general condition after the local infective process has been satisfactorily dealt with. At the same time it will be advisable to consider how far the administration of an anæsthetic is likely to be injurious. If the general condition is on the whole good, radical local treatment under anæsthesia should be resorted to; if, on the other hand, constitutional disease is advanced, the minimal amount of local treatment necessary should alone be attempted.

A second detail of practical importance in connection with the pathology of carbuncle is the fact that the vessels in the substance of the inflamed area being in a state of infective thrombosis, there is danger of the spread of systemic infection or pyæmia. Carbuncles on the face or scalp are especially dangerous, since the free communication between the superficial veins and the cranial venous sinuses renders the latter liable to fatal thrombosis.

The patient must be liberally fed and well supplied with alcohol, the bowels should act freely, and every effort be made with tonics, iron, and quinine, to improve the general health. If the pain is excessive, morphia may be given, though the need for this drug must be made subservient to the state of the kidneys.

LOCAL TREATMENT consists in :—

1. Complete excision of the whole infected area wide of the disease; this can be practised only occasionally, but is very satisfactory, the resulting wound, after thorough disinfection, being lightly packed with gauze and allowed to granulate.

2. Scraping out the gangrenous core, and the application of pure carbolic acid. It has been urged against this line of treatment that there is some danger of the clots becoming dislodged and carried into the circulation, with the result that pyæmia is set up. If the operation is carried out thoroughly, so that the deep fascia at the bottom of the wound is well exposed, and all the indurated tissue at the periphery of the necrotic area is radically treated, there is little danger of this accident occurring; it is much more likely to supervene if the operator is over-cautious, and merely stirs up the centre of the process with a timid hand.

3. I have lately treated a number of carbuncles, especially in debilitated subjects to whom I have been disinclined to administer a general anæsthetic, in the following way. The carbuncle is fomented until the central core softens, and then a small piece of lint is cut the exact size of the carbuncle, and soaked in the following: glycerin of carbolic acid 1 part, glycerin 1 part. The soaked lint is then applied to the carbuncle accurately; a small piece of oiled silk is placed over the lint, and the whole is covered with a gauze dressing. If there is any tendency of the lint to shift, it must be kept in place with strapping. I have found this method very satisfactory, and the glycerin excites a free flow

of lymph. Care must be taken, however, that only a small piece of lint is used, as the solution of carbolic acid is very strong. Good feeding and tonics are essential adjuncts to successful treatment. I am less inclined to operate on carbuncles than formerly.

4. Incisions, usually crucial, may be made into the swelling, and 5 to 10 minims of pure carbolic acid injected into various points of it. The wound is then fomented and the dead material allowed to slough out.

Bier's suction treatment (q.v.) has given good results in the treatment of boils and carbuncles.

Under all conditions it is wise to apply fomentations (carbolic) to assist the sloughs to separate, and a careful eye must be kept on the wound, since the pus occasionally has a tendency to burrow away into the surrounding tissues.

As soon as the sloughs have separated and healthy granulations have made their appearance, the wound should be dressed with protective, and if the epithelium is slow in covering the surface of the wound, skin-grafting may be employed.

W. H. Clayton-Greene.

CARCINOMA OF THE COLON.—Cancer of the colon can be very successfully treated by operation, and excellent results have been obtained both as regards the patient's subsequent comfort and freedom from recurrence of the tumour. Everything depends upon an early diagnosis before metastasis has occurred and while the growth is still well localized to the bowel wall, the exact situation of the growth being a very important factor.

It is necessary to distinguish between operations for cancer of the colon *per se*, and operations undertaken for acute obstruction due to cancer of the colon. In the latter case the operation is undertaken primarily for the obstruction, and it may often be necessary to perform a second operation for the removal of the growth. The best results in such cases are probably obtained by resection of the growth and bringing out the two ends of the bowel, the temporary colotomy thus formed being subsequently closed by a second operation. When obstruction is not present at the time of operation, the operation will consist in resection of the affected portion of bowel, the surgeon being careful to allow a good margin of healthy bowel on each side of the growth, and to remove as far as possible the lymphatic field draining the affected area. This may sometimes involve considerable removal of the mesocolon, and great care must be taken to ensure that the blood-supply to the ends of bowel which are about to be anastomosed has not been seriously interfered with. After the removal of the growth the ends of the colon may either be joined end to end by direct suture, or the ends may be closed and then joined by lateral anastomosis, or the ends may be brought out of the abdomen, as in Paul's operation, and a temporary colotomy established, the spur being subsequently divided by an enterotome and the external opening closed by a second operation. This last method, although it may involve two or even three operations, and although it puts the patient to the inconvenience of a temporary colotomy, appears from statistics to be by far the safest method, and it is the one which should be adopted except in very favourable cases.

Summary.—

1. In cases where acute obstruction is present at the time of operation, a temporary artificial anus should be made, or the growth should be excised and the ends of the bowel brought out.

2. At least an inch of normal bowel should be removed on each side of the growth.

3. Whenever possible the lymphatic area should be cleared with the growth.

4. Immediate end-to-end anastomosis after excision is safer when dealing with the right half of the colon than when dealing with the left half.

5. Colotomy followed by excision is a safer operation than excision with immediate anastomosis.

6. The presence of enlarged glands or adhesions to other structures does not necessarily contra-indicate resection.

J. P. Lockhart Mummery.

CATARACT.

Anterior and Posterior Polar Cataracts do not, as a rule, require any treatment.

Complete Congenital Cataract.—These cataracts are often—though by no means always—associated with other defects, both general and ocular. Thus the child may be badly nourished, slow in development, deficient mentally, or there may be microphthalmus or other signs of imperfect ocular development, or signs of past inflammation of the iris or ciliary body.

It is well known that operations on these cases are often disappointing in their results, or they run a complicated course. This does not necessarily contra-indicate operation—for many cases do well, and those which do not do well are little worse off than they were before; but it should make us very careful to give a guarded prognosis, to examine the child very thoroughly, and to operate only when it is in the best possible state of health.

Age for Operating.—The sooner the child can be made to see, the better for its mental development, and for establishing ocular co-ordination. The operation can be performed immediately the cataract is discovered, even in the first few weeks of life, if the health be good. Later on, teething is no deterrent to operation, unless it is impairing the health, in which case any operative procedure should be postponed.

These cataracts are either fluid, or they contain soft lens matter, or on the other hand they are shrunken, hard, even calcareous, or membranous.

When they are fluid, needling is all-sufficient; when they contain soft lens matter, a curette evacuation in addition may be necessary later on. (It is important to recognize that in some of these cases the pupils do not dilate with atropine; it is advisable here to do a small iridectomy upwards before needling, lest the swollen lens lying behind the contracted iris push this forwards and produce a glaucomatous attack—an awkward complication at this age and in so small an eye.)

In the shrunken form needling should be tried first; but it may be ineffective, and then the capsule may have to be removed bodily with forceps, in order to obtain a clear opening.

Lamellar Cataract.—As this condition often impairs the sight only slightly, it is, as a rule, only discovered either at the beginning of or during school life. We therefore meet with these cases at a time of life when it is possible to estimate the acuteness of vision.

We must determine: (1) Which cases should be operated on: and (2) What operation should be selected.

Though many cases of lamellar cataract get normal acuteness of vision with glasses after operation, yet vision of $\frac{6}{12}$ must be considered a good result, and patients have often to be content with $\frac{6}{18}$. We may take it, therefore, as a good working rule, that if the vision is $\frac{6}{12}$ or better, no operation should be undertaken; if the vision is worse than $\frac{6}{18}$, an operation may be advised. Vision of $\frac{6}{18}$ forms, as it were, a dividing line. If patients are healthy and intelligent, an operation is advisable; if mentally defective, operation will probably not improve the acuity. It must be remembered, in weighing the pros and cons of operation, that by removal of the lens all accommodative power is lost, and the patient is rendered entirely dependent upon glasses. Two pairs have to be carried, one pair for distance, and one for close work; so that for some individuals vision

of $\frac{0}{18}$ with accommodation and without glasses may be more useful than greater acuity with entire dependence upon spectacles.

OPERATION.—There are two different methods of improving vision in lamellar cataract : optical iridectomy, and removal of lens by needling.

Iridectomy is useful only when the opacity is small, and the periphery of the lens is clear, and when atropine, by dilating the pupil beyond the opacity, improves the vision very considerably. It has the great advantage that accommodation is left intact.

As a rule, unfortunately, the periphery of the lens is so irregular in its refraction that a good retinal image is not obtained through the coloboma. It is absolutely contra-indicated if the vision is deteriorating. If a needling has subsequently to be resorted to, a coloboma is a great disadvantage—being a disfigurement and a cause of dazzling, by producing a large and irregular pupil.

Needling aims at removing the opaque lens and giving a clear pupil—the place of the lens being taken by spectacles.

For details of operation, see works on ophthalmic surgery.

After-treatment.—The main points are the prevention of iritis, keeping the pupil well dilated to allow the soft lens matter to pass through into the anterior chamber, and watching the tension of the eye, lest the accumulation of soft lens matter induce secondary glaucoma. If this occurs, the soft matter must be let out by a curette evacuation. Evacuation is frequently necessary when the lens swells up rapidly three to eight days after needling ; and, indeed, without any rise of tension many surgeons remove the soft lens matter to hasten the clearing up of the lens. The eye is kept bandaged for at least four days, a round of cyanide Gamgee tissue being used as dressing.

The main dangers of needling are :—

1. *Sepsis.*—Prevention thereof by scrupulous asepsis is all-important ; but should this unfortunate accident take place, an immediate attempt should be made to save the eye. (See SENILE CATARACT.)

2. *Increased Tension.*—As mentioned above, this is treated by letting out the soft lens matter, and keeping the pupil well dilated with atropine.

3. *Iridocyclitis.*—Treated by leeching to the temple, hot bathing, atropine, purging, and rest.

Traumatic Cataract.—For the treatment of complications arising immediately after injury of lens, see EYE, INJURIES OF.

Most cases of traumatic cataract are *monocular* and complete, and we have to decide whether an operation is advisable. The cases may be divided into two classes : (1) Those in which the other eye is normal ; (2) Those in which the eye with the traumatic cataract is the better one of the two.

1. Cases in which the other eye is normal. The advantages of removing the cataract are :—

a. To increase the field of vision. This is the chief advantage ; and it is of great importance, both to those who follow an occupation dangerous to one-eyed individuals (e.g., mechanics and sportsmen), and those whose occupation under such conditions is a danger to the public (e.g., coachmen, chauffeurs, etc.).

b. To improve the appearance—substitution of a black pupil for a white one. (A man may be unable to get a suitable occupation if one eye is unsightly.)

On the other hand, intra-ocular operations, especially upon injured eyes, are not unattended by risks. To cause sympathetic ophthalmia and blind the good eye in trying to gain a slight increase in the field of vision, is little short of a tragedy both to the patient and surgeon.

Also, it must be remembered that, however successful the operation may be, *binocular vision* will never be regained. The eye without its lens, even though supplemented by a strong convex glass, never works in double harness with a

normal eye. Therefore, operation on a monocular cataract must never be undertaken lightly, and without having duly considered whether the risk is worth running for the particular individual.

2. Cases in which the eye with traumatic cataract is the better eye must, of course, be operated on; care being taken that both the patient and the eye are in the best possible state for undergoing the operation.

It may be stated generally of both these classes:—

a. Where the cataract has been caused by concussion, without penetration of the globe, and where there has been little or no cyclitis following the injury, operation—needling, with curette evacuation where necessary—may, as a rule, be performed with a good chance of success; cases where the cataract has been due to a penetrating injury, followed by severe and prolonged cyclitis, stand interference badly.

b. No operation should be attempted:—

i. Till at least two months have elapsed since all traces of injection of the eye have disappeared.

ii. While any keratitis punctata is present.

iii. If the projection is not perfect.

iv. In the presence of conjunctivitis or mucocele.

Senile and Complicated Cataract.—In dealing with a case of cataract we must find out whether the lenticular opacity is the sole disease, or whether it is complicated by some other ocular disorder.

1. The history should be obtained as to how long the sight has been failing; whether there has been any injury, pain, or sign of inflammation; whether the sight was good or bad, short or long, before the vision began to fail.

2. The pupil should be tested, and examined for adhesions, as indicative of past iritis.

3. The cornea should be examined for opacities or keratitis punctata indicating cyclitis.

4. The depth of the anterior chamber must be noted.

5. The tension must be carefully examined (to exclude glaucoma complicating the cataract.)

6. Tremulousness of either lens or iris must be noted.

7. The vision should be tested; any improvement that may be obtained with glasses being recorded.

8. The opacity in the lens is next investigated*; the type of cataract being noted, and whether it is *mature* or *immature*. (A cataract is *immature*, when the cortex of the lens is not yet opaque; and *mature*, when the opacity extends throughout the cortex as far as the capsule of the lens. The two conditions are distinguished clinically by means of oblique illumination: thus, in immature cataract, the cortex being clear, the iris throws a visible shadow on the cataract; while in mature cataract, the opacity extending to the capsule, the shadow of the iris is not visible.)

9. The fundus should be examined, if possible, and a note of the macula, when visible, should be made for future reference. If the opacity be too dense for examining the fundus, then—

10. The projection of light must be tested. Bad projection would indicate some disease in the fundus, e.g., optic atrophy, detachment of the retina (possibly associated with sarcoma of the choroid), or some other severe disease of retina and choroid.

* A mydriatic (one drop of a 2% aqueous solution of homatropine and cocaine) should, as a rule, be given to ensure the best possible view being obtained. This must be followed by instillation of eserine (2 gr. to the ounce) to prevent a possible attack of glaucoma.

11. Conjunctivitis and mucocele of the lacrymal sac should be carefully looked for.

12. The urine must be examined, especially for albumin and sugar.

With a history of defective sight, previous to failure of vision, especially when due to very high myopia, one must suspect the possibility of central macular changes and a fluid vitreous; hence, a guarded prognosis is given. We have to be prepared for some vitreous being lost at the time of extraction, and the scoop may have to be used, and convalescence is likely to be prolonged.

If there are signs of iridocyclitis, an interval of at least two months should elapse after all signs of active inflammation have disappeared before operation is attempted.

If increased tension is present, a preliminary iridectomy for the glaucoma is indicated.

If the iris or lens is tremulous, the suspensory ligament is probably faulty. Vitreous will very likely be lost, and the lens will have to be delivered with the scoop.

Cataract with bad projection should not be operated on.

Extraction is contra-indicated in the presence of *conjunctivitis*, and still more so in the presence of a *mucocele*. This latter should be treated by conservative methods first, and, if they fail, the sac should be excised previous to the removal of the cataract.

If sugar be present in the urine, an attempt should be made to reduce it by dieting and drugs before operating. Those cases in which the sugar can be reduced do well, as far as operation is concerned, though a previously invisible diabetic retinitis may vitiate the result. Those cases in which sugar is not influenced by dieting as a rule do badly.

Cases with albumin should be given a guarded prognosis, and one must expect a somewhat prolonged convalescence; but if the general health is good, albumin is not a contra-indication to operation.

Monocular Cataract.—When the cataract is monocular, no trace of lenticular opacity being found in the other eye, the cataractous eye must be most carefully examined for some associated disease (history of blow; signs of past or present iridocyclitis, keratitis punctata, etc.; signs of retino-choroiditis in either eye, or detachment of the retina with faulty projection; signs of glaucoma). Even if the eye be found otherwise healthy, it is only in exceptional cases that a monocular cataract should be operated on. (See TRAUMATIC CATARACT, *supra*.) *N.B.*—Monocular cataract associated with bad projection should always suggest the possibility of intra-ocular growth.

Double Cataract.—The degree of cataract is as a rule different in the two eyes. No operation should be undertaken while the vision of the better eye is $\frac{6}{12}$ or more. The only exception to this is if the more mature cataract is becoming *hyper-mature*, when the extraction may be performed earlier.

If one cataract is mature, or nearly mature, and if vision in the good eye has fallen below $\frac{6}{12}$, an operation should be done in the worse eye, so that this may be ready to be used as the vision of the other deteriorates. An operation done sooner is of little use, since an eye with $\frac{6}{12}$, with its lens *in situ*, is much more useful than even a $\frac{6}{6}$ eye, supplemented by a strong convex glass, but minus its lens.

Immature Cataract.—It is unnecessary to wait until maturity is reached; though mature cataracts are undoubtedly more easy to remove, and convalescence is less complicated, yet operations on immature cataracts, in patients older than fifty-five, as a rule do very well.

When both eyes are equally affected, and the cataract is immature, it is well to wait till vision has fallen to $\frac{6}{24}$ before operating. A preliminary iridectomy

may be undertaken; it often hastens the maturing process, and renders the extraction less liable to complications.

Having indicated the methods of determining which cases are suitable and unsuitable for operation, we have now to consider *how we can help the patient till the time of operation has arrived.*

1. We prescribe those glasses which give the best vision. A reasonable use of the eyes—short of causing discomfort or aching—is quite allowable.

2. If the cataract is chiefly nuclear, wearing of tinted glasses out of doors is of assistance, since they help to prevent the pupil contracting in a bright light. Weak atropine drops, $\frac{1}{10}$ to $\frac{1}{4}$ gr. to the oz., may be used once a day, just sufficient to dilate the pupil beyond the border of the opacity. In some cases, though unfortunately in very few, this is of great assistance. Care must be taken that the atropine—even though so weak—does not cause increase of tension.

3. The aching and discomfort often caused as the lens is swelling is sometimes relieved by alternate hot and cold bathing of the eyes, or by very weak atropine drops.

4. As mentioned above, in immature cataract in both eyes, a preliminary iridectomy may be performed to hasten maturation.

As regards the operation of extraction, see text-books on ophthalmology.

MANAGEMENT OF A CASE AFTER CATARACT EXTRACTION.—The patient is kept in bed for a week, with strict nursing for at least four days, and is not allowed to sit up till the end of the fourth day. Both eyes are kept bandaged for three days. If the patient is liable to hypostatic congestion of the lungs, he is allowed up sooner than a week, and to sit up in bed before the fourth day. If he has delusions, he should also be allowed to get up sooner, and the bandage should be taken off the unoperated eye at once.

Dressing.—The eye is dressed every day: warm boracic lotion is used to wash away any discharge from the lids, a little being allowed to pass into the conjunctival sac. The best dressing is a pad of cyanide Gamgee tissue. Great gentleness and strict antiseptic precautions are to be observed. No extensive examination of the wound should be made till at least the fourth day, if all is going well. The pupil must be kept well dilated with sterilized atropine drops or ointment (1 per cent), placed in the conjunctival sac once a day as a rule; but if the pupil remains contracted it must be used more frequently (see below, COMPLICATION, *Iritis*). At the end of the week, if the wound has healed, the anterior chamber has re-formed, and the eye is not injected, the bandage may be dispensed with during the day, and a pair of dark goggles worn. A pad and bandage should, however, be used at night for at least another week.

As to hobbling the patient's hands, it is well to tie a light bandage round the wrist at night on the same side as the operated eye, to prevent his knocking the eye in his sleep.

If all goes well, and the eye is free from redness, the patient may go out at the end of a fortnight; but care must be taken for at least a month to protect the eye from cold winds. Glasses are ordered six weeks after the operation.

Should *needling* be necessary, this should not be undertaken till two weeks after all redness has disappeared from the eye, but should not be postponed too late, lest the capsule lose its elasticity.

COMPLICATIONS.—1. *Suppuration.* If this occurs, the eye is in great danger of being lost, but eyes in which suppuration has begun have been saved by prompt and thorough action, viz., by washing out the anterior chamber and giving the appropriate vaccine. After an anæsthetic has been given, the aqueous humour is drawn off into a sterilized syringe, from which smear-preparations and cultures are subsequently made, the organism recognized and separated,

and the vaccine prepared. Having drawn off the aqueous humour, the anterior chamber is washed out with hydrogen peroxide or sterilized normal saline. The infection being usually due to one of the staphylococci, a mixed staphylococcal vaccine is given at the time, till the patient's own vaccine can be prepared. The after-treatment consists in the application of atropine, leeching the temple, regulation of the bowels, and maintaining the general strength of the patient, combined with absolute rest in bed. Suppuration is best prevented by the strictest antiseptic precautions, and by refraining from operation in the presence of conjunctivitis or a mucocele.

2. *Iritis* should be treated by atropine, leeching, hot bathing, and purging; if the pupil does not dilate well, the atropine should be inserted three or four times a day (sterilized atropine ointment is more efficacious than drops) till good dilatation is obtained; protection of the eye must be maintained proportionately longer. Should atropine irritation occur a substitute must be used. (See *IRITIS*.)

3. If the anterior chamber does not re-form, or if the wound does not properly flatten down, the use of the pad and bandage must be continued, and the patient kept in bed and at rest for a longer period.

4. Occasionally increased tension occurs. This, if due to cyclitis, must be treated as in 2. If due to entanglement of the capsule, weak eserine may be tried; division of capsule must not be attempted till other means have failed.

5. If the eye has not settled down in three weeks' time, and especially if the iris is muddy, the cornea hazy, and there is keratitis punctata, the danger of sympathetic ophthalmia must be considered, and a careful watch kept on the other eye. (See also *OPHTHALMIA, SYMPATHETIC*.)

6. In some cases of iridocyclitis following extraction of cataract, wonderful improvement has occurred after the administration of salvarsan—which can be repeated once or twice if necessary.

CELLULITIS.—(See *ERYSIPELAS*.)

CEREBELLUM, AFFECTIONS OF THE.

The cerebellum is prone to the same morbid conditions as affect other parts of the central nervous system, but it so happens that some of these are infinitely rare here, though common elsewhere. Thus, although liable to vascular lesions, these are seldom met with, so that embolism, thrombosis, and even hæmorrhage are rare events in connection with the cerebellum, although hæmorrhage in the pons not uncommonly invades the cerebellum by way of the fibres of its middle peduncles. When these accidents occur, they are to be dealt with on precisely the same lines as are recommended for their treatment when the cerebrum, or any other part of the central nervous system, is concerned. The fact that the cerebellum happens to be the seat of the occlusion or rupture of the blood-vessel does not in the least influence the main lines of treatment. It is, however, necessary that any local measures which are adopted for the relief of the condition when the cerebellum is concerned should be directed to the occipital region. The general measures of treatment are precisely similar, but in insisting on the need for physical repose, it must be remembered that an acute vascular lesion in the cerebellum or its peduncles may result in so much disturbance of co-ordination as actually to cause forced movements of the patient, which have accordingly to be restrained by physical means if that repose is to be obtained which is so necessary for the patient's well-being, notably when hæmorrhage is the lesion responsible for the symptoms.

The cerebellum shares, with other parts of the nervous system, the liability to congenital defects, in which atrophy or mal-development may occasion symptoms by which these defects can be recognized. Abnormalities of the kind may exist alone, or in conjunction with similar defects of the cerebrum, in which case the cerebellar deficiencies give a special colouring to the clinical picture of cerebral diplegia or whatever other form of congenital cerebral defect is under observation. There are, however, in addition, diseases in which a congenital weakness permits of atrophy of the cerebellum itself, or of those tracts in the spinal cord which form part of the cerebellar system. Friedreich's ataxy supplies a good example of the class of disease in which these anomalies are met with, and in which the spinal part of the cerebellar system is affected. There are, however, others in which the cerebellum is the only part in which defects can be determined, while in some, although the spinal cord is intact, other parts of the cerebellar system, including, it may be, the inferior olives, are involved.

In all these affections it is important to adopt general measures calculated to improve nutrition, and thus attempt to combat the tendency to decay which is going on in the nervous system. A liberal diet, fresh air, and sunshine, may with advantage be supplemented by nerve tonics, including notably arsenic and iron, and by cod-liver oil and preparations of malt. Massage and electrical treatment are useful to improve the general tone, as well as the state of the muscles. In addition, passive movements, and various forms of exercises, may be needed for the correction or prevention of deformities which have resulted, or are likely to do so, from the defects in the nervous system. The lateral curvature and condition of pes cavus so characteristic of Friedreich's ataxy serve as illustrations of defects of the kind that may have to be remedied in this way. In addition to this, however, exercises of a special kind are needed in the treatment of these cerebellar affections, exercises calculated to improve the power of co-ordination of the movements. No better system of exercises can be adopted for this than that introduced by Fraenkel, more especially for the treatment of the inco-ordination of tabes, but equally applicable to the treatment of cases in which cerebellar deficiency accounts for the instability. By means of such exercises, nerve centres hitherto not specially concerned in the co-ordination of movements are educated to take on this new work. Paths hitherto not much used for this are opened up for the transmission of impulses concerned with the regulation and co-ordination of movements, and the muscles themselves are taught how to do their share in the attempts to compensate the defects which permit of the inco-ordination. (See *TABES*.)

The cerebellum may also share, with the rest of the nervous system, some general disease, of which no better example is forthcoming than disseminated sclerosis. The chief importance of recognizing this is not so much from the point of view that any special treatment is called for in this malady in virtue of the fact that the cerebellum is affected, but rather because the defects occasioned by the implication of the cerebellum may give such a strong colouring to the clinical picture as to lead to the belief that an affection of the cerebellum, rather than a more general condition of the nervous system, is under observation. The mistake may thus be made of regarding as due to a cerebellar tumour a condition which is in reality the outcome of disseminated sclerosis, and the error of diagnosis may have the further disadvantage that so grave a misfortune as the undertaking of an operation for the removal of the tumour may result when in reality no tumour exists. The importance of avoiding the possibility of such an error makes it evident that too much care cannot be exercised in the diagnosis when cases of the kind are under consideration.

It is when the cerebellum is the seat of a tumour or abscess that we are most often called upon to advise treatment. In both cases, the only treatment that

offers any possibility of cure is an operation for the removal of the tumour or evacuation of the abscess. Apart from the seat to which it is directed, and the special risks which attend manipulative measures in this region, these operations are conducted on similar lines to those which guide the surgeon when he is interfering with other parts of the cranial cavity. The following considerations are, however, worthy of note :—

The optic neuritis which results in cases of cerebellar tumour is liable to be very intense, and to pass rapidly on to atrophy of the optic nerves ; so that when the operation of trephining, with a view to saving sight, is under consideration, it ought not to be too long delayed, lest permanent blindness result in spite of the operation, which has not been undertaken early enough. Another important consideration is that, in tumours of the cerebellum, as in the case of all sub-tentorial tumours, the effects of direct pressure on the medulla are great, and thus sudden death from arrest of respiration is especially liable to occur in these cases. If, therefore, an operation is to be undertaken with a view to prolong life, even when no attempt is to be made to remove the tumour, it were well not to delay too long ; for respiration may cease suddenly at any time in these cases, and then it rarely, if ever, happens that relief of pressure, aided by artificial respiration, is capable of saving the patient's life.

In the after-treatment of cases in which tumour or abscess has been successfully operated on, the special exercises recommended for improving co-ordination should be employed. The recovery of the normal powers of co-ordination, after the successful evacuation of an abscess in the cerebellum, is usually so rapid as rarely to call for any special measures of the kind, but it is otherwise when tumours of the cerebellum are concerned. In these cases, in addition to massage and faradism to improve the tone of the muscles and remedy any paralytic defect that may be present, exercises like those of Fraenkel, especially intended for improving co-ordination, should form a part of the treatment recommended.

J. S. Risien Russell.

CEREBRAL ABSCESS.—Localized collections of pus within the cranial cavity may lie between the bone and dura mater (extra-dural abscess) ; between dura mater and pia-arachnoid (meningo-cortical or subdural abscess) ; or within the brain substance (intra-cerebral or intra-cerebellar abscess). Any or all of these varieties may occur together, and the fact that intracerebral abscess is not infrequently multiple should never be forgotten. The micro-organisms concerned are most frequently the common pyogenic cocci ; less often the *pneumococcus*, *bacillus pyocyaneus*, and *bacillus typhosus* have been found. The commonest route of entrance is via diseased bone, and in this manner tuberculous and syphilitic caries of bone may cause intracranial abscess, but in such instances the abscess is due to the pyogenic organisms which have secondarily infected the diseased bone. Suppurative otitis media is by far the commonest cause. The chronic cases are more frequently complicated by abscess than the acute in the proportion of 9 to 1. Males are more often attacked than females, and the commonest age is from ten to thirty. In addition to bone disease, bronchiectasis and pyæmia are occasional causes. The actual modes of invasion are : direct extension via veins or perivascular lymphatics, direct infection by a penetrating wound, hæmatogenous infection of a damaged portion of brain, and embolism from some septic focus elsewhere.

In the bone cases, the abscess is usually situated close to the position of the caries ; so that in the ear cases it lies in the temporal lobe just above the tegmen tympani, or close to the anterior margin of the cerebellar hemisphere ; in the nose cases, in the frontal lobe.

The cerebrum is affected more than twice as often as the cerebellum.

With intracerebral abscess, all degrees of acuteness and chronicity are met with, from a diffuse purulent encephalitis with no boundary but œdematous brain, down to the strictly localized cyst-like abscess with a thick dense capsule. The capsule varies in thickness, and bud-like extensions are common; such buds are apt to become cut off from the parent and form apparently separate and independent abscesses. These advances may occur after a period of latency, causing fresh symptoms; and rupture may occur into the ventricles, or into the subarachnoid space. In the otitic cases the intracerebral abscess is frequently only one of a number of septic complications, such as meningitis, extradural abscess, lateral sinus thrombosis, and pyæmia.

The clinical picture varies as much as the pathological condition. Several types may be recognized: (1) Extremely acute diffuse septic softening of the brain, with rapid onset of œdema, compression, coma, and death; (2) Latent cases, with few symptoms until death occurs suddenly from œdema cerebri, or rupture of the abscess (such abscesses have been known to evacuate themselves spontaneously through the ear); (3) Cases of moderate acuteness, with steady advance of symptoms; (4) Very chronic cases, with symptoms indistinguishable from those of cerebral or cerebellar tumour.

TREATMENT.—Drainage of the abscess at the earliest possible moment is the only rational treatment. The cases reported as having recovered spontaneously represent merely pathological curiosities or diagnostic errors. The operation necessitates, as a first step, removal of the diseased bone from which the abscess has originated; and as the two are usually situated close together, this preliminary step opens up the natural and proper path for approaching the abscess.

Exploratory puncture with trocar and cannula is to be condemned on several grounds: the danger of carrying fresh infection into the brain substance; the improbability that the thick viscid pus will run along a cannula unless the latter be of very large size; the danger of passing the trocar through the abscess without detecting its presence; and the danger of pushing a thick-walled abscess away bodily, or causing a thinned-out advancing portion of its wall to rupture into the ventricle. If an exploration has to be made, it should be done by a clean incision with a sharp knife. The bony and dural openings must be large enough to afford a good view of the cortex before the incision is made. As soon as the intracranial pressure diminishes, from evacuation of the pus, the brain falls away from the surface and opens up the subdural space, thus inviting the spread of pus over the meninges. In order to avert this accident, strips of gauze should be tucked in between the dura and brain before the incision is made, thus packing off and guarding the subarachnoid space—just as the peritoneal cavity is packed off before opening into an appendix abscess. The best form of drain is an ordinary rubber tube with a gauze strip passed down its lumen. The frequent renewal of this strip keeps clear the lumen, which otherwise is very liable to become blocked by brain debris and thick pus. The tube may be shortened daily, and soon removed altogether, as the cavity quickly becomes obliterated by the falling together of its soft walls. Protrusion of brain substance is apt to occur at first from œdema, but this, in the absence of meningitis, soon subsides. Fungus cerebri occurring at a later stage points either to imperfect drainage, spreading encephalitis, or meningitis.

Percy Sargent.

CEREBRAL HÆMORRHAGE.—(See APOPLEXY, COMA, AND HEMIPLEGIA.)

CEREBRAL IRRITATION.—The train of symptoms known by this name is due to a laceration or contusion of the frontal lobes. On recovering from concussion the condition of the patient becomes one of extreme mental irritability. Absolute rest and quiet are essential, and the patient should be

disturbed as little as possible for the purpose of examination. It is undesirable that the patient should be forcibly fed by means of a nasal tube, and it should be remembered that often he may be persuaded to take food voluntarily, or will eat it if it be left by the side of the bed. Although the patient may have fairly recovered in two or three weeks, persistent mental weakness is not unlikely to remain; prolonged rest should therefore be insisted upon. The withdrawal of 20 c.c. of cerebrospinal fluid by lumbar puncture has been recommended in these cases, and is said to cause alleviation of the symptoms of restlessness and excitement. Such a measure, however, is contra-indicated if symptoms of severe compression are present.

CEREBROSPINAL MENINGITIS.—(See MENINGITIS.)

CERVICAL RIB.—(See NERVES, PERIPHERAL, SURGICAL AFFECTIONS OF.)

CHALAZION.—(See EYELIDS, DISEASES OF.)

CHANCROID.—The chancroid is a local contagious ulcer of the genital organs, is infective in nature, and is usually considered to be due to inoculation with the streptobacillus of Ducrey. This form of venereal disease was formerly met with very frequently, but is nowadays an unusual occurrence. As these sores tend to spread locally with great rapidity, and early to infect the inguinal glands, the primary object of treatment is the destruction of the bacillus. To effect this, iodoform, or one of its equivalents (see SYPHILIS), may be applied after the sore has been carefully cleansed in warm water. But if the ulcerative process does not subside under this treatment, then more strenuous measures must be adopted, consisting of application of carbolic acid, nitric acid, or Ricord's paste, composed of equal parts of sulphuric acid and finely powdered willow charcoal. By these means the infective process will be stopped, and the resulting ulcer may then be treated with antiseptic powders or lotions.

The chancroid is liable to be complicated by phimosis, a condition by which the multiplication of the sores is encouraged; under these conditions, sub-preputial irrigations with mild antiseptic lotions should be employed, and if this does not check the progress of the ulcers, free incision down the dorsum of the prepuce should be resorted to. The sores being exposed, they will subsequently yield to treatment by applications of iodoform or one of its substitutes; they are usually too extensive to admit of treatment by any cauterizing agent.

Chancroidal Bubo is a frequent concomitant of the chancroid, and is liable to proceed to suppuration should the bacillus of Ducrey be conveyed by the lymphatics to the inguinal glands, the condition being then known as virulent bubo. This will not yield to palliative measures, but requires free opening, scraping, and the subsequent application of antiseptic dressings. With the object of averting this possible complication, the patient should be enjoined to abstain from muscular exercise, such as walking, riding, or dancing, and a simple diet with abstinence from alcoholic drinks is essential. *J. Ernest Lane.*

CHICKEN-POX.—(See also FEVERS, ACUTE INFECTIOUS.) This disease is usually of so trivial a nature as to require no treatment except confinement to bed until all the vesicles have become scabs. Irritation of the skin and itching will be relieved by sponging with tepid boracic lotion, or by moistening the skin with a 2 per cent solution of carbolic acid. The child should be

prevented from picking the pocks; if there be much eruption on the scalp, the hair should be cut short.

If the pocks become gangrenous, the constitutional symptoms may be severe. The sloughing pocks must be fomented with warm boracic lotion till the crusts have separated; the ulcers that remain must be treated with a stimulating antiseptic lotion or ointment, and the patient put on a generous diet.

In the rare variety, varicella bullosa, the excoriations left by the ruptured bullæ require treatment with some such application as zinc or boracic ointment.

The patient may be considered to be free from infection when all the scabs have separated, or, in the case of V. gangrenosa, when the ulcers have healed.

Quarantine period: three weeks.

E. W. Goodall.

CHILBLAINS.—The general and prophylactic treatment is the same as in RAYNAUD'S DISEASE (q.v.). Cod-liver oil, maltine, and tonics should be administered. A course of thyroid treatment is often beneficial. Locally, the following applications are useful:—

R Caustic Potash	½%	Alcohol	aa 20%
Glycerin		Water	60%

The hands are bathed in warm water and the above rubbed in.

R A 30% ointment of ichthyol in lanolin or vaseline.

R Linimenti Aconiti (B.P.)		Olei Amygdalæ Amaræ	℥v
Linimenti Belladonnæ (B.P.)	aa 3iss	Linimenti Saponis	q.s. ad 3ij
Tincturæ Opii	3iij		

½ to 1 dr. is applied to the painful part night and morning.

Another method consists in immersing the parts once or twice a day in warm water, with subsequent gentle friction with camphorated alcohol, and powdering with one part of salicylate of bismuth to nine parts of starch.

The use of peroxide of hydrogen has also been strongly recommended. The patient bathes the affected parts in peroxide of hydrogen (10 vol.) diluted with equal parts of previously boiled water, still hot, for fifteen or twenty minutes twice a day. This treatment can be carried out even if the chilblains are cracked and ulcerated, though it is well to diminish the strength of the peroxide if much pain or irritation is produced by the application. Two or three days' treatment is usually sufficient. If there be much suppuration, chinisol fomentations (1–200 to 400) are useful, but if there be none, carron-oil dressings or a mixture of lanolin, vaseline, and almond oil in equal parts may be applied.

Recently, the administration of soluble salts of calcium has been recommended in order to increase the coagulability of the blood. The chloride or lactate may be given in doses of 10 to 15 gr. thrice daily, for two or three days at a time, flavoured with syrup of orange or fluid extract of liquorice. Very good results have been reported in some cases.

For electrical treatment, see ELECTROTHERAPEUTICS.

Robert Hutchison.

CHLOROFORM or POST-ANÆSTHETIC POISONING, DELAYED.—These commonly used terms are unfortunate, as they imply that the long series of fatalities, with symptoms ascribed to fatty acid intoxication (see VOMITING, CYCLICAL) following administration of an anæsthetic, is due to the specific action of the anæsthetic in producing fatty metamorphosis in the liver and other organs.

Chloroform, repeatedly inhaled for long periods by animals, will induce such fatty changes, but it is incredible that they can result from inhalation of amounts of chloroform not exceeding 1 dr. during short and trivial operations.

Ether and other anæsthetics given experimentally will not produce fatty changes in the liver comparable to those produced by chloroform, yet precisely

similar fatty livers are found post mortem in fatal cases, whether chloroform or ether was the anæsthetic employed. It follows, therefore, that the characteristic intense and universal fatty metamorphosis of the liver, found after death from so-called delayed chloroform or post-anæsthetic poisoning, cannot be the effect of the anæsthetic alone. Some other factors must be present, and these are probably the same as are concerned in the production of acidosis, acid intoxication, and cyclical vomiting (q.v.).

The rôle of the anæsthetic is that of the "last straw." If oxidation in the liver and tissues be already deficient owing to the presence of acute sepsis, microbial infection, or auto-intoxication of intestinal origin, the effects of a general anæsthetic may be to lower oxidation still further, to reduce metabolism, and to hinder elimination of noxious products by the liver and kidneys. The part played by shock, fright, and starvation antecedent to the operation, has perhaps been exaggerated. In not a few cases the operation has been short and trivial, evidence of shock or fright has been absent, and the patients have been well nourished and in no sense starved.

Hepatic inadequacy to utilize fats and carbohydrates, because they have been supplied either in absolute or in relative excess, may cause a condition of "foie gras." The functions of a superfatted liver are liable in such cases to break down at any moment, and the administration of an anæsthetic will precipitate what is really an attack of cyclical vomiting with acetonæmia. But, as previously mentioned, the acetone bodies are not poisonous, and although toxic symptoms arise in cases of acetonæmia, it is extremely doubtful whether so-called fatty acid intoxication is ever fatal. Probably "post-anæsthetic poisoning" is due not only to failure of the liver to metabolize fat, but to the breaking down of all its functions, proteolytic, glycogenic, and antitoxic.

Howland and Richards have found that innocuous doses of phenol and indol given to animals become toxic when the ability of the cells to take up oxygen is diminished by administration of chloroform or potassium cyanide. The results were marked gastro-intestinal congestion, necrosis and degeneration of the liver cells. It is therefore probable that the result of an anæsthetic may be to render highly virulent comparatively harmless intestinal toxins and organisms. The *symptoms* resemble those of acute yellow atrophy of the liver, and although in children the condition found is one of intense generalized fatty infiltration only, with perhaps scattered areas of slight necrosis, in adults there can be no doubt that true acute yellow atrophy sometimes follows anæsthesia by chloroform (Ballin). The difference is probably one of degree merely. Autolysis of the hepatic cells in acute yellow atrophy is the final effect of a virulent toxæmia.

The conclusions offered with regard to delayed chloroform and post-anæsthetic poisoning are:—

1. That it is a condition of acute toxæmia, of which acidosis and fatty acid intoxication are but symptoms.
2. That the toxæmia may be organismal, or may be due to absorption of intestinal poisons with which the liver is unable to deal.
3. That such hepatic inadequacy may be potential and imminent, owing to previous storage of fat in the liver cells resulting from diet excessive in fat and carbohydrates, and want of exercise.
4. That hepatic inadequacy to deal with fat stored in the liver cells explains cases of cyclical vomiting with acidosis, and that the subjects of cyclical vomiting are potential victims to post-anæsthetic intoxication.
5. That in such conditions any general anæsthetic acts as the "last straw," by decreasing oxidation already failing or on the verge of failure, and by preventing elimination by the liver and kidneys of noxious products.

6. Fright, shock, and precedent starvation may join in determining a fatal issue, but are not jointly or severally responsible.

7. The theory that idiosyncrasy to chloroform accounts for post-anæsthetic fatalities is untenable, because they may occur after administration of any general anæsthetic. Moreover, some patients who have succumbed after chloroform anæsthesia have taken chloroform with impunity on previous occasions.

TREATMENT OF DELAYED CHLOROFORM OR POST-ANÆSTHETIC POISONING.—The accepted treatment of post-anæsthetic poisoning is based on the assumption that acid intoxication is the cause of the symptoms. Carbohydrates are recommended to supply the oxygen necessary for the conversion of fat, and alkalies to neutralize the fatty acids supposed to be present in excess, or to take the place of alkalies drained for a similar purpose from the tissues.

As fatty acids are not highly toxic in themselves, it is believed by some that the symptoms are really due to diminished alkalinity of the blood and tissues. Benedikt, however, has found that the alkalinity of the blood may be far lower than it ever is in diabetic coma, without the occurrence of toxic symptoms.

Whatever may be the explanation, it seems certain that the alkaline treatment has been serviceable in a few cases of incipient diabetic coma with acidosis. This treatment should therefore be employed in post-anæsthetic intoxication:—Drachm doses of citrate or bicarbonate of potash or soda should be given in three or four ounces of water every three hours per rectum, as fluids cannot be retained in the stomach. Half to one pint of normal saline solution should also be injected intravenously, and repeated if necessary twice daily.

A temporary rally is all that the writer has observed as the result of this treatment in severe cases. The same may be said of strychnine given subcutaneously, and of hemisine, $\frac{1}{100}$ gr., in the form of "ophthalmic tabloids," placed in the conjunctiva or under the tongue. Restlessness, excitement, and delirium should be treated by bromides in $\frac{1}{2}$ - to 1-dr. doses per rectum. On no account should morphia or chloral be given.

The Carbohydrate Treatment is suggested by the fact that under its use the acetone bodies speedily disappear from the urine in cases of diabetes.

The theory that post-anæsthetic intoxication is simply a matter of carbohydrate starvation is against all clinical experience, yet carbohydrates as oxygen carriers may be of use.

Dextrose in 10 to 20 per cent solution given per rectum,* or in 6 per cent solution intravenously as suggested by Beddard, has been successful in at least one case.

The treatment of severe cases of post-anæsthetic intoxication is most unsatisfactory, but many mild cases of prolonged vomiting and acidosis recover under simple measures, such as giving ice to suck, or frequent sips of hot water, and applying hot fomentations to the epigastrium.

Prophylaxis.—There is reason for believing that the subjects of "cyclical vomiting" are also potential victims to post-anæsthetic intoxication. A clear history of cyclical vomiting has been obtained in some cases. The chief danger seems to be in operating on patients just before, or during, an attack of acute acidosis. Operations after or in the intervals between attacks of cyclical vomiting seem to be free from danger. Operations, again, in cases of chronic acidosis have been performed without ill result. This seems to be further evidence that post-anæsthetic poisoning is not merely an acid intoxication, but a far graver form of toxæmia.

Caution should be exercised in performing any but urgent operations on children who are subject to cyclical vomiting. When excess in fats and carbohydrates has been habitual, a mixed diet, with restriction in those articles, should be prescribed for two or three weeks before an "operation of expediency" is

* Solutions over 10 per cent strength are likely to induce painful intestinal cramp.—AMER. ED.

undertaken.* The anæsthetic employed should always include oxygen. Chloroform alone is especially dangerous, and ether, ethyl chloride, and even nitrous oxide, are not safe. Perhaps A.C.E., or nitrous oxide with oxygen to follow, would be attended by least risk.

When with marked acidosis operations for conditions such as acute appendicitis appear urgent, one can only counsel delay so far as seems consistent with safety.

Leonard G. Guthrie.

CHLOROSIS.—(See ANÆMIA.)

CHOLANGITIS.—(See BILE-DUCTS, CATARRH OF.)

CHOLECYSTITIS.—Inflammation of the gall-bladder may be catarrhal, suppurative, or phlegmonous.

Simple catarrh of the gall-bladder is frequently associated with that of the ducts, the catarrh commencing in the gall-bladder and spreading into the ducts, or vice versa. And the causes of the two affections are much the same—very commonly it is a gall-stone in the gall-bladder, but perhaps more often than in catarrh of the ducts it arises from some general blood infection or some local abdominal lesion which leads to a microbial affection of the gall-bladder.

Treatment is the same as that of catarrh of the biliary ducts (see BILE-DUCTS, CATARRH OF).

A peculiar form of inflammation of the gall-bladder sometimes occurs in which the catarrhal products result in coagula or partial or complete casts of the interior of the gall-bladder. This gives rise to spasmodic attacks of pain, resembling attacks of biliary colic, though on the whole of less severity. So much do they resemble biliary colic that the gall-bladder has been opened on a diagnosis of gall-stones.

The treatment is the same as that of chronic catarrh of the ducts, viz., by cholagogues and salines. Acetyl-salicylic acid is spoken of as giving great relief during the attacks. If the affection be very persistent, it is best to open and drain the gall-bladder.

Suppurative and phlegmonous inflammations of the gall-bladder give rise to empyema of the gall-bladder or to sloughing of its walls; they occur sometimes from gall-stones, sometimes from a virulent microbial affection, as has occurred in some cases of typhoid fever.

The treatment is immediate operation, and drainage or excision of the gall-bladder.

Sidney Phillips.

CHOLELITHIASIS.—(See GALL-STONES.)

CHOLERA.—(See also SPECIFIC THERAPY.) During an epidemic great care must be taken in the treatment of all disorders of the alimentary system, as these in many cases predispose to attacks. Any diminution in the normal acidity of the gastric contents decreases the natural protection against this disease.

At the onset of the disease a brisk purgative is of value; calomel, castor oil, or castor oil and opium, are those most frequently used. When the disease is established, no powerful drugs must be given by the mouth in large quantities, as little absorption takes place from the stomach. Not only may such drugs be useless, but a portion may remain in the stomach to be absorbed during the period of reaction, and so prove injurious.

Intestinal antiseptics such as β -naphthol, izal, and salol, have been frequently used, but without very beneficial results. Rogers uses permanganate of potassium or calcium to destroy the toxins in the intestine. He uses a solution

* Opie and Alford have found that carbohydrates protect the liver cells, in white rats, from the necrosis caused by chloroform, and that chloroform is much more toxic to rats on a fat than on a meat diet.—AMERICAN EDITOR.

of $\frac{1}{2}$ to 1 gr. per pint, and rapidly increases the strength to 4 to 6 gr. if the patient will swallow it, and allows the patient to take this solution *ad libitum*; or he gives it as 2-gr. pills. More frequently the treatment is directed towards relieving the symptoms. Such mixtures as the following seem to give relief:—

R. Acidi Sulphurici Diluti	℥xxv	Tincturæ Capsici	℥v
Chlorodyni	℥xx	Aquam Menthæ Piperitæ	ad 3j

Every two hours.

Hot applications to the abdomen, warmth, and rest as far as possible, must be enforced. Hypodermics of morphia or inhalations of chloroform to relieve cramp may be given.

In the collapse stage, heat is essential and may be supplied by the use of warm blankets, and hot-water bottles to the feet, thighs, and axillæ. Injections of ether and strychnine may be required. Transfusion with normal saline solution sometimes produces marked benefit, but this is often temporary, and though the transfusion may be repeated, its effect is then less marked. There is often a recurrence of the diarrhœa. Rogers' treatment by intravenous injection of hypertonic saline solution gives better results. The solution he uses is composed of 120 gr. sodium chloride, 6 gr. potassium chloride, and 4 gr. of calcium chloride to 1 pint of sterile water. In a bad case of collapse he gives 3 or 4 pints at a rate of not more than 4 oz. per minute; both the rate and the amount depend on the variation in the blood-pressure. The injection should be repeated if collapse recurs. During the stage of reaction, treatment must be entirely symptomatic and not too active.

C. W. Daniels.

CHORDEE.—(See GONORRHOEA.)

CHORDITIS TUBEROSA.—(See LARYNGITIS.)

CHOREA, ACUTE RHEUMATIC.—When considering treatment, it is necessary to take a broad view of the various factors, in addition to the rheumatic infection, that have a part in the causation of chorea. It is also useful to keep clearly in mind that for rheumatic chorea we have two outstanding indications for treatment. The first is the rheumatic process; the second the nervous phenomena which arise from the result of the damage to the nervous system produced by this rheumatism.

Rheumatic children are often highly nervous, very sensitive, and lacking in reserve force. They frequently suffer from night terrors and headaches, and are easily upset by shocks and frights. A knowledge of this will sometimes enable us to anticipate an attack of chorea. Such warning symptoms as headache, dreaming of school work, fidgety movements, irritability, slight fever, and loss of mental and physical powers, call for active measures. All school work should be stopped, and the child be kept in bed, or at most allowed upon a couch in the afternoon, and later may rest in the fresh air. The bowels should be well opened, and only light food allowed. In this stage some believe that full doses of sod. salicyl. or acetyl-salicylic acid will cut short the illness, even if they are given when definite choreic symptoms have appeared. My experience leads me to believe that if good results are to follow from these drugs, it is under such circumstances. I prefer salicylate of sodium to acetyl-salicylic acid, and when using it prefer having the child at complete rest. When chorea is severe or has been present for some weeks, I do not advocate pushing these drugs, for they do not seem to have any effect upon the illness.

Although rest is advisable in these mild cases of chorea, we are compelled to use our judgement as to the exact degree of restraint. Early signs of heart disease imperatively call for the utmost care, but where the heart escapes and

the patient is unmanageable in bed, it may be essential and proper to relax the strictness of the "rest cure." Severe cases, the tests of which are the inability of the child to feed itself, to control its emotions, and above all to sleep, require most careful and skilful nursing. In order to prevent injury from the violence of the movements, the bed must be thoroughly padded, and although it is not permissible to use active restraint, a good nurse will certainly help the child by firmly tucking the clothes round it whenever it shows an inclination to sleep. Slight injuries and bedsores are difficult to prevent, for the skin becomes dry and unhealthy from the exhaustion of the child, and the incessant movements strongly dispose to their occurrence. If bedsores do arise, there is a peculiar liability to the supervention of septicæmia. The greatest quiet must be insisted upon, and isolation from other children, or even from everyone except competent and quiet nurses, may be called for. Here again we must use our judgement, always remembering that a child's mother may be by far the best companion, and that there is no magic in the term "trained nurse." The food should be fluid, nourishing, and abundant, and in exceptional cases nasal feeding is needful. Milk, eggs and milk, strong soups, and jellies are all indicated in these severe cases, and if large doses of hypnotics are being given, stimulants are of great service. It is in the cases of this severe type that the second indication for treatment becomes paramount. We are compelled to deal with the nervous phenomena, and I do not think at the present time we can do this by anti-rheumatic treatment, logical and desirable though this may be. For the worst cases, the most valuable drugs, in my opinion, are chloral hydrate and bromide of potassium, and it is seldom that any decided signs of cardiac failure occur in children when treated with these. The chief difficulty lies in leaving off the chloral, for experience shows that, when it is omitted, there may be considerable nervous disturbance. This is most likely to arise when the physician has been alarmed by signs of collapse, and on this account has abruptly stopped the chloral. In most cases the difficulty can be overcome by cautiously diminishing the dose, and substituting occasionally a small dose of another hypnotic, such as veronal.

Another admirable plan is the use of a hot pack given morning and evening. This is often followed by a refreshing sleep.

A considerable amount of judgement is required in the management of chloral and bromide. These drugs should be pushed sufficiently to produce drowsiness, but, whenever it is possible, the interval between any two doses should be increased, although on no account should the child be allowed to become very restless. For a child of seven years the following prescription can be given at the commencement :—

R Chloralis Hydratis	gr. vij	Aquæ Chloroformi	℥ss
Potassii Bromidi	gr. x		
Ft. mist. Mitte ℥vj. One tablespoonful every four hours.*			

The dose can be raised to 10 gr. of chloral hydrate, and such stimulant as is given should follow the medicine. Instructions should be given to the nurses to be on the watch for coldness of the extremities. Throughout the illness, the bowels, which are often obstinate, should be kept well opened. When the urgency is over and the child left exhausted by the illness, quiet is still imperative, and any inclination to sleep should be encouraged. A liberal diet should be allowed, and arsenic can now be given in an alkaline solution, thus :—

R Liquoris Potassii Arsenitis	℥iij	Spiritus Chloroformi	℥vj
Sodii Bicarbonatis	gr. vj	Aquæ Destillatæ	q.s. ad ℥ss
Ft. mist. Mitte ℥vj. One tablespoonful three times a day after meals.			

Later, massage should be commenced, and if the weather is suitable the child

* Such doses would be considered excessive by American physicians.—AMERICAN EDITOR.

can soon be wheeled into the fresh air. Should it be noticed that, although the health appears to be restored, the movements remain choreiform, then passive exercises combined with suggestion are useful, and such toys and games as favour co-ordinate movements should be chosen. Lastly, when walking is permitted, Swedish exercises are indicated.

In many cases of moderate severity, one advises rest, feeding, and careful massage. The bowels are regulated by aperients, and no further medical treatment is needed.

Dr. Voelcker has obtained good results from trional given in doses of 5 gr. in cases of acute chorea, and I have certainly seen decided improvement in some very difficult cases; yet it is also sometimes very disappointing.

Chloretone has been warmly advocated, but my experience has not been so decisive in its results as to enable me to be enthusiastic about this method. Like all the sedative measures, it does quiet the child, for it has a powerful action, even in 5-gr. doses, but many cases do not seem to get better any the quicker. Of this, too, I am convinced: you may with these doses get well-marked toxic symptoms, the direct result of the drug. The practitioner must be on guard for ataxy, slight double ptosis, mental apathy, and an extensive papular or erythematous rash. I place it among the many drugs that by their sedative action seem sometimes to suit cases admirably and at other times to be ineffectual.

A favourite drug in the treatment of chorea is arsenic. Some use it in ordinary doses, others commence with moderate doses, and rapidly push it to the limit of tolerance. Others commence at once with large doses, e.g., 10 to 15 min. of liquor potassii arsenitis. I never myself use arsenic in rheumatic chorea when the temperature is raised, and in severe cases it seems to me valuable time is lost by its routine employment. When there is no fever, and the nervous rather than the infective element predominates, arsenic sometimes produces marked improvement, and it is in this class of case that I use it. If it be decided to push the drug, its toxic symptoms must be remembered, such as vomiting, irritation of the eyelids, silvery tongue, looseness of the bowels, abdominal pain, and dermatitis. Three severe cases of neuritis have come under my observation, the results of the undue prolongation of this method of treatment. The dose at first is 5 min of liquor potassii arsenitis three times a day, and is raised drop by drop until 10 or even 15 are given. When the maximum is reached, it is maintained for a week, and then the treatment abandoned. As the dose of arsenic is increased, so must be the bulk of fluid in which it is prescribed, for it is the concentrated arsenical solutions that are especially liable to damage the digestion. A useful device is to give the drug in barley-water flavoured with lemon.

A very great number of drugs have been used in the treatment of chorea, as phenazone, ergot, conium, belladonna, strychnine, and quinine, but their success is very doubtful, and I am convinced that in a case of ordinary severity it is wiser to trust to the healing power of nature than to give a child large doses of powerful drugs. Throughout the illness a close watch must be kept for the onset of carditis.

Vaccine therapy, so far as I have as yet employed it, has not produced any good result, and in one case I am inclined to think it had some influence in increasing the severity of the movements, but any statements of value upon the treatment of chorea need the support of numerous and accurate observations.

F. J. Poynton.

CHOREA, CHRONIC.—*Exercises* are prohibited in all acute cases of chorea. They are only of use when, although heart, pulse, temperature, appetite, and

digestion are normal, all pains and aches have disappeared, and general health has seemed fully restored for some weeks, choreic movements still continue.

Such may be termed *residual* chorea. The movements have become habitual, and may be chronic if untreated, but usually soon yield to carefully graduated exercises. These should be of the simplest character at first. Taking and crowning the pieces arranged on a draught-board, or building houses with small wooden blocks, should be practised. Freehand drawing and writing large letters with coloured chalks on a black-board; touching, at word of command, small coloured balls hung at varying heights by strings to a frame; aiming with a pointer at the different circles of a target: all are useful and easy exercises as a commencement. More difficult are building card houses and setting backgammon pegs in holes drilled in patterns into a board.

Threading needles, sewing, and writing in small text should be left to the last. Many other useful exercises can be taken from the kindergarten apparatus. The principle is, to keep those which require the greatest amount of precision and co-ordination until the easiest have been mastered. No exercise should be employed if it tire or bore the patient.

For slouching, clumsy gait, ungainly attitudes, humped shoulders, dropped chins, all of which are sometimes sequelæ of chorea, ordinary drills are essential. (See also HABIT SPASMS.)

Leonard G. Guthrie.

CHOREA GRAVIDARUM.—In the majority of cases the patient, with the exception of the fact that she has involuntary movements, goes through a normal pregnancy, has a normal labour, and brings forth a normal child. If the movements have not ceased before labour, they probably will do so during the next month or two.

The frequency with which spontaneous abortion occurs, and also the tendency to the occurrence of acute maniacal attacks, have been exaggerated. It is possible that abortion is more common in these cases than in pregnancy uncomplicated by chorea, and it is true that acute maniacal attacks do occur, by which the patient is worn out, but these grave cases are rare. Most attacks of emotional insanity, whether maniacal or melancholic, are transitory, and not of grave prognostic significance.

The treatment may be summed up briefly thus: Assure the patient that the probability is that she will have a normal labour and eventually recover. Endeavour to find out whether she has any source of worry. Make her sleep, give her plenty of nourishment, and keep her in bed in a quiet room with good nursing until the movements cease. Good nursing is essential, otherwise bedsores will probably develop. In many of these cases the exciting cause is to be found in mental worry, anxiety, or some shock. Removal of the source of worry, e.g., dread of difficulty and danger in the approaching confinement, will often have a marked effect in improving her condition. Marriage, in cases of illegitimate pregnancy, is to be advised as a part of the treatment.

The patient must be made to take a liberal diet, containing a large proportion of carbohydrates; in fact, "over-feeding" is necessary. If the patient refuses to take food—a rare occurrence—forced feeding must be resorted to. Dr. Cecil Wall has pointed out a most important fact in connection with the difficulty occasionally met with in getting these patients to take food, viz., that a dental ulcer may be present, due to the frequent movements of the tongue against a sharp tooth.

The patient *must* sleep. Light massage and "nursing" are preferable to drugs as methods of inducing sleep. If sedatives are necessary, chloral hydrate or chloralamide, combined with alcohol, are the drugs most to be recommended. They need not be given in large doses as a rule, nor need they be frequently

repeated. Iron is indicated in cases where there is anæmia. The value of arsenic is very doubtful. Acetyl-salicylic acid seems to act as well in chorea gravidarum as it does in ordinary chorea. Induction of abortion is to be avoided if possible. Formerly this method of treatment was responsible for many deaths from sepsis, and even at the present time there is some danger of sepsis following induction of abortion, the constant movements of the patient rendering asepsis difficult to obtain, in spite of the most minute precautions. This method of treatment, if ever employed, must be reserved for the small percentage of cases in which emaciation, sleeplessness, and the violence of the movements are exhausting the patient's strength. As, however, in these more severe cases induction of abortion is not always followed by improvement, and always brings with it a new danger, it is not to be resorted to lightly.

Another method of treatment, advocated by Drs. Fothergill and Fletcher Shaw, is based on the theory that chorea of pregnancy is a manifestation of toxæmia. Dr. Fletcher Shaw's routine treatment is "to keep the patients quiet in bed, on a diet restricted entirely to milk, until the movements show signs of improvement, when the diet is very gradually increased, always returning to the milk if there is any increase of the symptoms. Elimination by the skin and kidneys is encouraged by administering a simple saline diaphoretic and diuretic mixture, and the bowels are kept well open by calomel and jalap." In more severe cases he gives a large dose of calomel, followed by an oil enema and simple enemata, a pint of saline solution per rectum every four hours, and thyroid extract 5 gr. by mouth four-hourly. He found that in twelve consecutive cases treated on these lines no hypnotic drugs were needed, natural sleep occurring generally on the second or third night.

H. Russell Andrews.

CHYLURIA.—(See **FILARIASIS**.)

CIRCUMCISION.—(See **PHIMOSIS**.)

CIRRHOSIS OF LIVER.—In the early stages of cirrhosis the symptoms may be but slight, and are frequently indistinguishable from symptoms due to associated perihepatitis or to the effects of alcohol upon the gastro-intestinal tract; in non-alcoholic cirrhosis the symptoms are few till quite late in the disease. Abstinence from alcohol will often lessen the flatulence, retching, and indigestion, but it is impossible to keep such patients under close observation, and the craving for alcohol being usually a part of the disease, abstinence from it is more often enjoined than observed; at any rate, it should be impressed upon the patients that alcohol is most injurious when taken little diluted, and when the stomach is empty. Cirrhosis is not always due to alcohol; it occurs in animals such as cows and cats; often no cause is to be discovered. Syphilis, congenital or acquired, is the cause in some cases, the liver being then lobulated, and perihepatitis usually marked. Alcohol, however, seems prejudicial in cirrhosis from any cause; so, too, are rich, irritating, or highly spiced foods, which often congest and enlarge the liver temporarily. Syphilitic cases often improve greatly under treatment by mercurials and iodides; experience is still required as to the value of salvarsan in these cases.

The best diet is said to be milk, but this dietary is impossible to carry out in men following an active occupation, who can only be advised to take plain and light food, and to drink water, or Vichy or Seltzer water, freely at meals.

The accompanying gastric catarrh is best treated by alkalies and bitters, the latter sometimes relieving the alcoholic craving. Abstinence from alcohol and care in diet and mode of living may sometimes succeed in staying the progress of the earlier stages of the disease.

In the late stages, the cirrhotic process continues even after alcohol ceases to be taken, but nevertheless abstinence from it should still be advised, as the contrary accelerates the disease. In these stages, the symptoms are due to obstruction in the portal circulation, to failure of liver function owing to destruction of hepatic cells, and often also to accompanying perihepatitis and advanced gastric catarrh.

Diarrhœa may be checked by astringents and by opium if necessary, but a laxity of the bowels lessens the tendency to ascites, and should not be abruptly stopped.

Constipation, on the other hand, must be dealt with gently, or intractable diarrhœa may come on. Small doses of calomel occasionally, and more frequently phosphate or sulphate of soda, are best.

Hæmatemesis and **Melæna** must be stayed by astringents and opium; in hæmatemesis adrenalin is also useful; but hæmatemesis may be repeated and profuse, and may fail to yield to any remedy. It is undesirable to operate on hæmorrhoids in advanced cirrhosis, the result being sometimes very profuse hæmatemesis.

Ascites is sometimes due to portal obstruction within the liver; not infrequently perihepatitis produces or contributes to its causation. Diuretics, of which oleum copaibæ is one of the most useful, may lessen it; iodide of potassium is also useful. Inunction with the linimentum hydrargyri (B.P.) seems to lessen it in some instances, but too often it persists. The fluid should then be drained off gradually by two or three Southey's tubes, which are preferable to the larger trochar and cannula. The abdomen, whether drained suddenly or gradually, usually rapidly refills at first; but tapping must be resorted to again and again. It is true that the ascitic fluid seldom fails to reaccumulate; but the tapping relieves discomfort and often enables the subject of it to continue at his work, which would be otherwise impossible. In some cases, after repeated tapings the ascites ceases. Tonics, including iron, are beneficial in helping absorption of ascitic fluid. Dickinson advocated great restriction of the amount of fluid taken. Local peritonitis, or sometimes hæmorrhage into the abdomen, may occur after tapping. When ascites persists after repeated tapping, operation has been practised, with the object generally of overcoming the obstruction to the return of blood through the portal circulation. Talma's operation consists in opening the abdominal cavity, the peritoneum over the liver and diaphragm is scraped or curetted, so as to set up adhesive inflammation, the surfaces are brought into contact by stitches, and an addition to the original operation is the inclusion also of the great omentum between the diaphragm and liver. Roberts, of Philadelphia, practises another operation, stitching the great omentum to the abdominal wall. Another operation consists in division of the portal vein and uniting its distal end to the ascending cava, thus diverting the blood from flowing through the liver. These operations have been attended with some measure of success. In many cases the ascites in cirrhosis is due to local perihepatitis, and mere breaking down of adhesions lessens it.

When grave toxæmic disorders begin in the late stage of cirrhosis, such as hæmorrhages from the skin and from mucous membranes other than those whose blood returns into the portal system, delirium, and typhoid conditions, little can be done except to tide patients over their most serious discomforts.

Sidney Phillips.

CLAUSTROPHOBIA.—(See AGORAPHOBIA.)

CLAW-FOOT.—(See TALIPES, ACQUIRED.)

CLEFT PALATE.—The deficiency in the palate may be limited to the soft part, or may extend to the hard palate as well; but a cleft of the hard palate without a cleft of the soft palate is almost unknown. The extent to which the hard palate is involved is very variable; there may be merely a notch on its posterior border, representing the smallest deficiency, or there may be a complete cleft extending from behind forwards over the whole extent of the palate, and involving the alveolar margin in front. Between these two extremes, all possible variations in extent of involvement of the hard palate are found. The cleft may be unilateral or bilateral: that is, the palatal process of the superior maxilla on one side may have united with the nasal septum, but union between the two superior maxillæ has not occurred, and so a unilateral deficiency is the result; when both superior maxillæ fail to unite with the nasal septum and with one another, a bilateral deficiency is the result. These variations, however, are of developmental rather than of surgical interest. The relations of the premaxilla to the anterior portion of the cleft are variable in cases of complete cleft. No union may have occurred between the premaxilla and the alveolar borders of the superior maxillæ on either side, and so the premaxilla juts prominently forward in front of the jaw, attached to the forepart of the nasal septum. Or union may have occurred on one side, so that the premaxilla appears rotated at its free edge away from the cleft separating it from the opposite superior maxilla.

With all types of cleft palate, varieties of hare-lip may be associated. (See HARE-LIP). In cases of complete cleft of the palate, early closure of the hare-lip appears to exert an influence tending to reduce the width of the cleft spontaneously. In incomplete clefts of the palate, this influence is absent, and so the presence of a hare-lip has no bearing upon the surgical treatment of the former. The view that the preliminary closure of the lip prevented proper access to the palate during later operative treatment is no longer tenable. The surgical treatment of hare-lip and cleft palate are therefore separate and independent problems in every case except in the type of complete cleft already alluded to.

The disabilities attending the presence of a cleft palate are: (1) Disfigurement, especially marked in cases of complete cleft; (2) Impairment of deglutition; (3) An imperfect mode of respiration when the nasal and oral cavities are not shut off from one another; and (4) Imperfection of pronunciation. The aim of the surgeon, therefore, is not merely to close the cleft, but also to remedy as far as possible the functional disability that is associated with it. As a rule, all of these disabilities readily disappear when the closure of the cleft has been effected—except the last one, defect of speech. This constitutes a separate problem. Perfect anatomical restoration of the palate does not necessarily imply perfect restoration of speech. The degree of speech defect previous to operation cannot be correlated with a corresponding degree of structural defect in the palate. "Cleft palate" speech is present as a congenital defect in some children who have no structural defect of the palate at all. Other cases with gross structural defects may have little imperfection of speech. Others, again, with only slight structural defects may have such a high degree of speech defect as to be almost unintelligible. It is not surprising, therefore, to find that in some cases in which the result of operation is anatomically good, the functional result is disappointingly poor; and vice versa, that with indifferent anatomical results, a quite disproportionate improvement in the speech has sometimes occurred. The theory that the speech defect partially depends upon the structural deficiency of the palate, and partially upon an associated lesion of the speech centres, affords some explanation of these anomalies. Education of the patient after operation plays an important part in improving the defects of pronunciation.

The most suitable age for operating, and the type of operation to be employed, are still matters for controversy. Those surgeons who delay until the patient is two or three years of age do so on the ground that the cleft becomes narrower during the growth of the child. This certainly occurs where the cleft is a complete one. But it does not do so to any appreciable extent in that type of incomplete cleft in which operative success is the most difficult to achieve—i.e., where the cleft involves the hinder two-thirds of the hard palate and is broader towards the anterior end. Their estimation of the right time for operation is further based upon the conclusion that the Langenbeck operation of paring the edges of the cleft is the method to be employed. That this method has not given universal satisfaction is suggested by the search for alternative methods, a search which has resulted in the evolution of the flap-sliding operation of Davies-Colley, the hinged-flap operation of Arbuthnot Lane, and the bone-approximation operation of Brophy. These methods have this advantage in common, that they can all be performed as soon as the child is strong enough to stand the strain of operation, and they are most opportunely performed within the first six months of life. Obvious disfigurement, imperfect deglutition, and impaired modes of respiration are thus abolished at an early date, whilst the surgical advantage of performing an operation in the mouth before the teeth are erupted is secured. Further, the tendency to catarrhal disorders of the respiratory tract is diminished. If the operation is successful, the training of the child in a correct pronunciation can be undertaken from the earliest moment at which it commences to talk. The chief disadvantage of these methods is the greater severity of the operation, which has led to fatal results in a certain number of cases, whilst if healing fails to occur, the successful performance of a secondary operation at a later date is rendered more difficult.

From a careful study of the end-results of all methods of operating, these facts emerge : that a high percentage of successes has been achieved by each method in the hands of various surgeons ; that the early results of most surgeons by any method are invariably poor. The conclusion is obvious that, for any operation, the road to success lies through the diligent attention to detail and technique of any one method ; and that success will not be achieved until the skill, which is the fruit of experience of that method, has been gained. As a personal experience, the writer has deliberately abandoned the use of Langenbeck's operation (in its entirety) and also of Brophy's operation, but with a full recognition of the fact that other surgeons have achieved considerable success by the use of these methods. His own use of the Lane flap-method for the hard palate, combined with the Langenbeck operation for the soft palate, appears to him to combine the best features of both operations and to avoid the disadvantages of either. The operation can be done at an early age, and, so far as the experience of the writer is concerned, has not been attended by any complications. The principal features of these various operations are as follows :—

1. **Arbuthnot Lane Flap Operation** (for the hard palate only).—As a preliminary, the premaxilla must be restored to its normal position (for details, see HARE-LIP) if the cleft is a complete one. The cleft then resembles the type shown in *Fig. 5*. In the actual case from which the sketches were made at the time of operation, the cleft was an incomplete one of the extent shown in the picture, without displacement of the premaxilla, and thus serves to illustrate the method of operation as applied to clefts of all sizes. From one side of the palate the mucoperiosteum is raised as a flap, which is then hinged on its mesial border across the cleft. In cutting the flap, particular care must be paid to designing it of such a size that it will easily bridge the cleft without tension, and in all cases the posterior palatine artery, which enters just behind and internal

to the site of the last molar tooth, must be preserved in its pedicle. With these precautions, no sloughing of the flap has occurred in any case under the writer's care. The free margin of the mucoperiosteum on the opposite side of the cleft

Fig. 5.—Flap being raised by special raspatory.

is then undermined and raised to receive the free edge of the flap. Apposition is secured by mattress sutures of fine silkworm gut, which are first inserted through the epithelialized surface of the flap and then through the raw surface of the raised mucoperiosteum of the other side (Fig. 6), emerging at some distance from its free edge. If these have been properly inserted, raw surfaces of about a quarter of an inch breadth on both sides should be held in firm contact with each other. The free edge of the superior surface is then firmly united to the raw surface of the flap by a continuous suture along its whole length (Fig. 7). This continuous suture is of great advantage in helping to secure firm union and healing.

beck method. By this time the hard palate is pared at its free edges, with the removal of the minimum amount of tissue, by means of a small scalpel or a sharp tenotome (Fig. 8). Guide sutures inserted at the apex of each portion serve to steady it in position while this is being done. The palate on each side is then cut away by means of curved intranasal scissors from its attachment posteriorly to the hinder margin of the palatal process of the palate bone. This serves to render easy the approximation of the raw surfaces, and to temporarily paralyze the action of the tensor and levator palati muscles. Again the use of the continuous suture is of great value in obtaining firm union. The material used is ophthalmic D. silkworm gut, threaded upon Lane's finest curved cleft-palate needles. Two layers are inserted, somewhat in the manner used for effecting an intestinal anastomosis.

The posterior margins of the free surfaces are first of all approximated by a continuous suture that passes between the posterior surface of the palate and the

is then undermined and raised to receive the free edge of the flap. Apposition is secured by mattress sutures of fine silkworm gut, which are first inserted through the epithelialized surface of the flap and then through the raw surface of the raised mucoperiosteum of the other side (Fig. 6), emerging at some distance from its free edge. If these have been properly inserted, raw surfaces of about a quarter of an inch breadth on both sides should be held in firm contact with each other. The free edge of the superior surface is then firmly united to the raw surface of the flap by a continuous suture along its whole length (Fig. 7). This continuous suture is of great advantage in helping to secure firm union and healing.

An interval of about two months is allowed to clapse before the second stage of the operation on the soft palate is undertaken by the Langen-

Fig. 6.—Mattress sutures in position.

raw surface (*Fig. 9*). A second suture passing from the raw surfaces to the anterior surface of the palate then completes the union (*Fig. 10*).

In *Fig. 11* the condition of the palate is shown at the completion of the second operation. At the junction of the hard and soft palate small openings may appear in some cases. Where very small, they tend to disappear spontaneously; but if necessary, they may be closed by freshening the edges and drawing them together with a purse-string suture.

During the operation, a sandbag is placed under the child's shoulders, so that the head slopes backwards and downwards, enabling the blood to trickle towards the nostrils and away from the larynx. A silk suture is passed through the apex of the tongue to act as a retractor, and the jaws are propped open by means of Lane's cleft-palate gags or by a modified O'Dwyer's gag with small metal spikes inserted into the mouth-pieces. All suturing is done with black-stained ophthalmic D. silkworm gut, threaded on Lane's cleft-palate needles held in his special needle-holder. The sutures are left in position until they drop out. At the end of the operation the palate is varnished over with a modified Whitehead's varnish (the spirit and iodoform are omitted from the original formula).

A mixture of oxygen and chloroform makes the most satisfactory anæsthetic, although open ether can be administered for these cases by a very expert anæsthetist.

Fig. 7.—Mattress sutures tied; continuous suture inserted.

Fig. 8.—Edges being pared.

Fig. 9.—Posterior continuous suture inserted.

Fig. 10.—Anterior continuous suture inserted.

2. Langenbeck's Operation (for the hard and soft palate combined).—The edges of the cleft are pared by a fine scalpel, with the minimum removal of tissue, over their whole length. Close to the alveolar margin of the jaw small incisions are made parallel to the cleft, through the mucoperiosteum of the hard palate, care being taken to avoid the site of the posterior palatine artery. These

incisions serve not only to relieve tension upon the line of union after the sutures have been inserted, but permit the introduction of a small raspatory beneath the mucoperiosteum, which is then gently detached from the hard palate as far inwards as the sides of the cleft. The edges are then brought together by means of interrupted stitches of medium silkworm gut, which are inserted at some distance from the raw margins. A small piece of tape may be passed from one lateral incision beneath the raised mucoperiosteum of both sides, and then, emerging through the lateral incision of the opposite side, be tied so as to relieve tension on the raw edges. The opposed edges of the soft palate are similarly approximated by interrupted sutures.

3. Brophy's Operation.—This is best performed during the first six weeks of life. The two superior maxillæ are forcibly drawn together by means of silver wires passed through them, until the edges of the cleft are almost in contact. These are then freshened and sutured in the ordinary way.

Fig. 11.—Completed operation at the end of both stages.

The bone is transfixed through the gum, at a level above the palatal process and just behind the malar process, by a special stout needle carrying a pilot suture of thick silk. The needle is withdrawn, leaving the loop of the suture hanging free in the cleft of the palate, and the process is then repeated on the opposite side. The two loops of silk are then engaged, and one of them is withdrawn, so that the other is carried across the cleft and emerges through the hole in the opposite maxillary bone. Silver wire is then hooked on to this thread, and by reversing the pull, the wire is made to occupy the position of the thread. Two more wires are similarly inserted through the jaw in front of this one, and they are finally secured in position by passing through holes drilled in small metallic plates placed upon the outer surface of the gum on either side. The wires are then twisted together with sufficient tightness to approximate the bony portions of the palate. Severe

osteitis, and even death, have resulted from this procedure; but undeniable successes have been achieved, especially in the hands of Brophy.

After-treatment.—If hæmorrhage should occur after any operation upon a cleft palate, an anæsthetic must be given and the bleeding point sought for. If the bleeding is coming from a bony foramen, simple pressure with a hard instrument to occlude the opening generally suffices, or the opening may be plugged by Horsley's aseptic wax. For general oozing, the local application of a strong solution of chloride of calcium is most valuable. The child must be kept quiet and prevented from crying by skilful nursing, eked out by the use of opiates when necessary. No local treatment to the palate is needed. Syringing and spraying must always be avoided, since they induce coughing and crying, which are a menace to the line of union. The use of a mixture of chlorate of potash and salicylate of soda as a four-hourly medicine helps to ensure a cleanly condition of the mouth. In older children, a mild antiseptic mouth-wash after food may be of value. Only fluid food must be given for ten

days after operation. This should have been sterilized previously, and must then be administered from sterilized receptacles. Infants must be spoon fed, and they should have been accustomed to this prior to operation.

The palate should not be examined until at least a week from the date of operation. Harm may be done by the resentment aroused by the examination of a palate that is healing successfully; whilst if it is not healing, no local measures are of any value in averting the break-down of the wound. Should septic infection have occurred, its onset will be heralded by a rise of temperature; but this is an exceedingly rare complication. The stitches are left *in situ* until they drop out. They may often be picked off the surface of the palate a few months after the operation.

George E. Waugh.

CLIMACTERIC.—(See MENOPAUSE.)

CLIMATIC TREATMENT.—(See HEALTH RESORTS.)

CLUB-FOOT.—(See TALIPES, ACQUIRED.)

COCAINE HABIT.—(See DRUG HABIT.)

COLD IN THE HEAD.—(See RHINITIS, ACUTE.)

COLIC (in Adults).—These patients should be induced to take regular exercise, or, if this is impossible, they should have general and abdominal massage, either by hand or by mechanical means (Zander apparatus). Where circumstances permit, a course of treatment at Marienbad is beneficial. If, as is often the case, the patient eats too much, the diet should be limited in amount, and the use of vegetables and fruit containing much cellulose forbidden.

The drug treatment must include the regular use of aperients, especially infusion of senna pods or liquid paraffin, taken daily, at night or in the morning. During the attack relief may be obtained by giving 10 min. of the carminative tincture (B.P.C.). Fifteen drops of Collis Browne's chlorodyne is an effective remedy, or 2 min. of the essential oil of cajaput, cloves, or peppermint, taken on a lump of sugar, or the following mixture :—

R. Tincturæ Opii	℥vij	Aquæ Menthæ Piperitæ	q.s. ad 3j
Olei Ricini	3ss		

To be taken at once.

(See also PLUMBISM.)

Robert Saundby.

COLIC IN CHILDREN.—In children flatulent colic occurring as a consequence of indigestion and fermentation of food is a common complaint. In hand-fed babies it may be due to over-feeding, to an inappropriate dietary, to want of cleanliness of the feeding-bottle, or to a chill setting up gastric catarrh; indeed, catarrh of the stomach is rarely absent, either as cause or effect. All these matters must be attended to, of course, without delay.

In children of all ages a very obstinate form of colic may be induced by the presence of a chronic post-nasal catarrh. This condition is accompanied by a copious secretion of mucus from the upper part of the nasopharynx. This is not only acrid and irritating in itself, but swarms with organisms and may be highly septic. The secretion trickles down the fauces and is swallowed by the patient. By this means a septic decomposition of the food is excited in the stomach, which leads to the formation of many noxious elements. These toxins may become absorbed into the system and be later the cause of wide-spread mischief; but an early consequence is often seen in attacks of severe

colicky pain which may resist treatment with some obstinacy unless the throat condition be attended to.

In most cases of colic the attack of pain may be arrested by a copious enema of hot water (95°–100° F.) slowly injected into the bowel, or by ten to fifteen drops of spirits of nitrous ether in a spoonful of water given by the mouth. The effect of the draught is to produce a discharge of flatus, followed by a copious flow of urine, and the pain ceases. Hot applications to the belly externally also help in promoting a dispersion of the wind. To prevent its recurrence, a dose of castor oil, or rhubarb and soda, should be given to clear away fermenting matters from the bowel. When this has acted the child may begin to take an antiseptic with carminatives. Thus for an infant of six months old :—

R Resorcini	gr ij	Tincturæ Cardamomi Co.	℥v
Spiritus Ammoniaë Aromatici		Aquæ Carui	q.s. ad ℥xxx
Spiritus Chloroformi	āā ℥ss		

To be given every three hours.

Ingluvin is also a useful remedy in doses of two grains every three hours ; also the sulphate of zinc medicine recommended for VOMITING (*q. v.*).

A more obstinate form of colic which resists most antifatulent remedies is sometimes met with in infants, both nursed and hand-fed. In nursing babies it is the consequence of the milk being too rich in protein. In this case the child shrieks with pain directly he has taken the breast. It is cured by giving the infant one or two ounces of fresh barley-water just before nursing, so that the milk is diluted as it reaches the stomach ; or by a grain of Finkler's papain in a spoonful of water immediately before the child is put to the breast. If the attacks are only lessened and not cured by this means, $\frac{1}{30}$ gr. of codeina, given two or three times a day, rarely fails of its effect. It may be ordered with

R Resorcini	gr ij	Glycerini	℥x
Sodii Bicarbonatis	gr j	Aquæ Anethi	q.s. ad ℥xxx

In hand-fed babies the same treatment may be adopted, putting the dose of papain into the feeding-bottle ; or we may add citrate of soda to each bottle in the proportion of one grain to each ounce of the milk. It must not be forgotten in these cases to introduce a sufficient variety into the dietary, giving at least two differently flavoured foods alternately in the day, and providing a third for the night ; also to see that the feet and legs of the child are kept warm. Cold feet alone may be a cause of colicky pains. Very obstinate cases are sometimes met with which resist even these measures. In one such case the infant was eventually cured by inunctions of mercurial ointment ordered as a last resource. The child had shown no signs of a syphilitic taint, and except for the abdominal derangement seemed to be perfectly healthy.

Older children are sometimes subject to attacks of severe abdominal cramp coming on repeatedly in the day and persisting for a week or more at a time. In the actual attack relief may usually be obtained by a rectal injection of one pint of hot barley-water containing half an ounce of oil of turpentine. To prevent a repetition of the pains every attention must be paid to the warmth of the feet and the avoidance of chill. The dietary must be revised, limiting the quantity of fermentable food, such as starches and sweets ; and a mild aperient must be given to clear away undigested matters from the bowels. A useful remedy in these cases is :—

R Olei Terebinthinaë	℥iv	Glycerini	
Olei Ricini	℥viij	Mucilaginis	āā ℥xv
		Aquæ Menthaë Piperitæ	q.s. ad ℥ij

Given every three hours (for a child six years old).

The mixture acts upon the bowels and stimulates the urinary secretion.

If there be much tympanites the turpentine may be combined with codeina and nitrous ether :—

℞ Olei Terebinthinæ	℥v	Glycerini	℥xv
Spiritus Ætheris Nitrosi	℥xv	Aquæ Menthæ Piperitæ	q.s. ad 3 ss
Codeinæ	gr 10		

To be taken every four hours.

At the same time it is advisable to lessen the quantity of milk allowed as food, and to give in preference pounded fish, mutton or chicken, rusk or toast buttered cold, etc.

In all obstinate cases, whatever be the age of the patient, it should never be forgotten to ascertain the presence or absence of post-nasal catarrh. This is especially important if the patient respond but sluggishly to the treatment. If the pharyngeal mucous membrane be noticed to be thick-looking, vividly red and, glistening with mucus, measures should be adopted without any delay to remedy this state of things, for a colic induced by a septic fermentation in the alimentary canal is often difficult of cure, or if arrested, very prone to relapse, as long as the introduction into the stomach of tainted mucus continues.

The colic which sometimes arises from an overloaded bowel can be distinguished by palpation of the belly, when the faecal masses may be felt as hard superficial lumps studding the course of the colon. Sometimes they can be indented by firm pressure with the fingers. To clear these away a full dose of calomel should be ordered, to be followed after a few hours by a saline aperient ; and the latter may be repeated every three hours or so until a sufficient effect is produced. The calomel has a marked influence in softening the faecal masses, but in cases of long standing it may be necessary to use purgative injections, and even to break up the hard lumps in the rectum by mechanical means, before they can be expelled. (See CONSTIPATION.)

The colicky pains which precede a stool in cases of lenteric diarrhœa are treated of elsewhere. (See DIARRHŒA, INFANTILE.)

Eustace Smith.

COLITIS.—(See also DYSENTERY.)

Catarrhal Colitis (Acute).—Acute or simple colitis is a catarrhal inflammation of the colon comparable to bronchitis or urethritis. There is usually persistent diarrhœa, which comes on suddenly, without apparent cause, accompanied by vomiting, pain in the abdomen, cramp in the calves of the legs, and signs of collapse. The distinctive character of the stools is that they contain much mucus and usually bright red blood. There may be a little elevation of temperature, but this is by no means constant. The following treatment may be adopted :—

1. The patient should be put to bed at once between hot blankets, hot fomentations should be applied to the abdomen, and hot bottles to the feet.

2. Gentle manual friction to the walls of the abdomen, the calves, and the thighs, will be found beneficial.

3. To a tumblerful of cold fresh cow's milk two tablespoonfuls of old liqueur brandy or old pot-still whisky should be added, and this should be sipped slowly.

4. A saturated solution of camphor in alcohol should be given in 3-min. doses every ten minutes for an hour, and subsequently hourly for six hours.

These measures will usually be found efficacious, but should they fail, and especially if the presence of an irritant in the intestines is suspected, a tablespoonful of castor oil should be given, followed in two hours by 20 min. of tinctura chloroformi et morphinæ composita (B.P.).

Other remedies which may be found useful are :—

1. Perchloride of mercury, $\frac{1}{2}$ gr. in 6 oz. of water, a drachm every ten minutes for an hour, and then hourly.

2. Grey powder, $\frac{1}{3}$ gr. every hour for twenty-four hours.

3. An enema of laudanum, 10 min. in an ounce of mucilage of starch at a temperature of 100° F. The dose should be smaller for children, not more than two thirds of a drop of the tincture of opium for every year of the child's age.

4. Pulvis kino compositus (N.F.), 10 gr. three times a day, with tincture of capsicum 3 min.

5. A hypodermic injection of morphine, $\frac{1}{3}$ gr.

Attention must be paid to dietary, and a selection may be made from the following list :—

(1) Barley-water ; (2) White of egg flavoured with lemon juice ; (3) Whey, preferably white-wine whey ; (4) Milk, with one-third lime-water, or peptonized.

For the treatment of colitis in children, see DIARRHŒA, INFANTILE.

Mucous or Mucomembranous Colitis.—This variety of colitis is peculiarly obstinate and difficult to treat. At the outset it is important to make as complete a diagnosis as possible, and to remember that "mucous colitis" may be merely a symptom of organic disease of the colon, such as carcinoma, or result from the pressure of tumours or partial obstruction by adhesions, etc. It is therefore always advisable to make a pelvic examination and, in many cases, to employ the sigmoidoscope, before beginning treatment. It must also be remembered that in many cases the disease is accompanied by a greater or less degree of visceroptosis, and that, in almost all, there is an underlying condition of neurasthenia which will require treatment on the usual lines (see NEURASTHENIA).

In all severe cases it is advisable to begin treatment with the patient in bed. Pain, which is due to enterospasm, should be relieved by hot fomentations to the abdomen, and by the injection of warm olive oil (4 to 6 oz.) into the bowel at night. This may be followed by a plain douche of normal saline next morning.

As regards diet, two plans are advocated : (1) One which is as bland and unirritating as possible ; (2) A bulky diet, rich in fat and cellulose, such as is useful in ordinary cases of constipation.

1. The former plan is that chiefly used in France, and is preferred by the writer. It consists of lightly-cooked eggs, pounded meat or fish, mashed potato, toast, rusks or biscuits, macaroni, vermicelli, and the other Italian pastes, purée of apple or prunes, and milk in small amount. All coarse and indigestible articles are forbidden, and no raw fruit or green vegetables are allowed, except perhaps purée of spinach.

2. The coarse diet, recommended especially by von Noorden, proceeds on diametrically opposite lines, and contains the coarsest whole-meal bread, and plenty of green vegetables, well-boiled and mashed with butter, in addition to pounded meats and much cream and butter.

After a fortnight or so of the above treatment, the patient may begin to get about, continuing the same diet ; but he should lie down for at least an hour after the mid-day meal. The injections should be discontinued and the patient encouraged to do as far as possible without aperients. It is rare, however, to find that these can be dispensed with altogether, but they should be of the least irritating kind. Castor oil (either at bedtime or on first waking in the morning), the infusion of senna-pods, regulin, phenolphthalein (purgin, laxoin, etc.), or, in the milder cases, liquid paraffin (half an ounce on an empty stomach twice daily) are the most suitable, the dose being regulated according to requirements. Salines and aloetic preparations should be avoided. In some cases a daily enema of plain warm water is sufficient. If there be any pain in the colon (enterospasm), belladonna should be given in addition (e.g., gr. $\frac{1}{2}$ of the extract, in pill, night and morning). Any tendency to dropping of the organs should be met by the use of a support (e.g., Curtis's), and abdominal exercises are often beneficial ; but massage is usually injurious, especially if there be any pain.

The morbid mental condition which these patients often exhibit is difficult to combat, but they should be encouraged to live a normal life and to interest themselves in outside things (see PSYCHOTHERAPY). Bromides are useful from time to time for nervousness or irritability, but strychnine is best avoided.

In some cases a course of treatment at a spa is useful. Plombières and Châtel-Guyon have both a high reputation, and many patients now go to Harrogate in this country, where the "ascending douches," which are an essential part of the French treatment are well carried out. Care must be taken, however, not to overdo the treatment by douching, although as an occasional measure it is helpful in cleansing the colon in the more chronic cases. Intestinal antiseptics, though often employed in this form of colitis, are disappointing in their results. Capsules of cyllin or kerol, or tablets of β -naphthol, are the best forms to employ. Soured milk gives good results in a few cases, but very often it fails to produce benefit. Surgical treatment is of little help in uncomplicated mucomembranous colitis. Ileosigmoidostomy alone is never to be recommended, and resection of part of the colon is a severe measure which is but rarely to be advised.

Ulcerative Colitis.—The treatment of the dysenteric form of ulcerative colitis is that of DYSENTERY (q.v.). The non-dysenteric form is best treated by appendicostomy. (See COLITIS, SURGICAL TREATMENT OF.)

Robert Hutchison.

COLITIS, SURGICAL TREATMENT OF.—The symptoms usually described as chronic mucous colitis may result from a great many abnormal conditions of the colon; in fact any irritative lesion of the colon may cause such symptoms. It is most important to realize this, as our first aim and object is to find the cause of the symptoms and if possible correct it.

The cause may be a chronic inflammation of the mucous membrane of the colon, either in its whole length, or more usually in part. It may be a chronically inflamed appendix which is constantly discharging septic material into the colon. It may be that there are adhesions, the result of some previous inflammatory mischief, binding down or kinking the bowel. The cause may be cancer of some part of the colon, the presence of some tumour pressing upon the colon, enteroptosis of the transverse colon, multiple polypi, or other similar conditions.

The first essential of treatment is a careful examination, if necessary under an anæsthetic. The abdomen must be carefully palpated, and the pelvis examined bimanually with one finger in the rectum. The most important examination is that of the higher part of the rectum and the sigmoid flexure with the electric sigmoidoscope. If any inflammatory condition of the mucous membrane be present, it will almost certainly be seen in the sigmoid flexure, and in many cases it is confined to this portion of the colon. The stools should also be carefully examined both macroscopically and microscopically.

In those cases in which, after a careful examination, a definite cause for the symptoms cannot be discovered, and in which a course of medical treatment has failed to give permanent relief, the advisability of an exploratory laparotomy should be carefully considered. The severity of the symptoms and the amount of incapacity for the ordinary affairs of life must be the determining factors in advising operation, as chronic colitis does not threaten the patient's life, except when ulceration is present.

If there is a local cause for the symptoms, such as adhesions, a tumour, or a chronically inflamed appendix, this will have to be dealt with according to circumstances. In those cases where there is a chronic inflammation of the mucous membrane of the colon which will not yield to medical treatment, the choice of operation lies between a right-sided colotomy and appendicostomy. Very good results have followed giving rest to the colon by means of a right lumbar or

right inguinal *colotomy*, but owing to the liquid character of the faecal material coming from the colotomy opening, there are serious objections to this procedure. *Appendicostomy* is a much better operation in these cases, and does not cause the patient any inconvenience. This operation consists in bringing the appendix out through a small incision in the right iliac fossa and stitching it to the skin. A few days later the end of the appendix is cut off, and the colon is then irrigated daily by passing a rubber catheter through the stump of the appendix into the caecum and allowing water, or some other suitable fluid, to flow into the colon from a funnel attached to the catheter. When the catheter is removed, the small opening of the appendix is both gas- and water-tight, and causes the patient no inconvenience. This operation is practically free from any risk, and has given very satisfactory results in these cases. It should be very seriously considered in those cases of chronic colitis due to inflammation of the mucosa which do not yield to medical treatment.

Chronic Ulcerative Colitis.—This is a much more serious condition, and many of the cases end fatally, either from progressive wasting or from perforation and peritonitis. Surgical treatment in these cases, if it is to be successful, must be carried out in the early stages of the disease, and not used simply as a last resort when the patient is almost dying. The indications here are to keep the colon clean and free from faeces and the products of inflammatory and putrefactive processes. This can be done either by performing appendicostomy, which enables the colon to be washed out frequently, or by entirely deflecting the faecal current by means of a right-sided colotomy. Appendicostomy is by far the best operation, and the results have been so excellent that there should be no hesitation in advising it directly ulcerative colitis is diagnosed. Although recovery will sometimes occur without operation, it is so tedious a process in such circumstances that most patients will much prefer the latter. Right-sided colotomy is only indicated in cases where appendicostomy fails to cause any improvement. The operation must be done as early as possible, and the opening should in all cases be preserved for some months, until all traces of blood and pus have disappeared from the stools, as tested by microscopical examination. The results of appendicostomy in the treatment of ulcerative colitis have been excellent; the mortality from this disease ten years ago was about 50 per cent, whereas now in the cases treated by appendicostomy the mortality has been reduced to under 5 per cent. Appendicostomy should be the routine treatment in all cases of ulcerative colitis, and the operation should be performed as early as possible. Right-sided colotomy should never be performed for this condition unless appendicostomy has failed and the patient is losing ground; it will but seldom succeed if appendicostomy has failed.

If a right-sided colotomy is performed, the opening will have to be closed later by a plastic operation. If an appendicostomy has been done, an operation to close the opening will not be necessary. The patient should continue to irrigate the colon daily with warm water, and this should be continued from six months to a year. If the patient wishes to have the wound closed, it can readily be done by cauterizing the mouth of the opening, a procedure which does not require an anæsthetic. As a rule, however, the patients do not seem at all anxious to have the opening closed, as it causes no inconvenience.

It is not advisable to use boracic lotion or other antiseptics for the purpose of irrigating the colon in cases of appendicostomy. Warm water or weak saline solution only should be used, unless there be some special reason for the use of antiseptics. The author has seen two cases of boracic acid poisoning through the use of boracic lotion in these cases. (See also CONGENITAL DILATATION OF COLON.)

J. P. Lockhart Mummery.

COLLAPSE.—This condition differs from SHOCK, SURGICAL (q.v.) in that the vasomotor centres in the medulla are not exhausted as in shock, but are either temporarily paralyzed (as in the case of a blow in the abdomen), or are unable to maintain the blood-pressure on account of a sudden diminution in the quantity of circulating fluid in the blood-vessels (as in hæmorrhage). The best treatment in cases due to hæmorrhage is saline intravenous infusion, combined with the head-down position and bandaging the limbs. In sudden collapse, artificial respiration should be carried out until the patient has recovered.

J. P. Lockhart Mummery.

COLON, CARCINOMA, CONGENITAL DILATATION, DIVERTICULITIS, OF.

—(See CARCINOMA, CONGENITAL DILATATION, DIVERTICULITIS, OF COLON.)

COLOTOMY (Colostomy).—By this is meant the formation of an artificial anus in some portion of the colon. Lumbar colotomy is practically never performed now, and the only operation is that through the abdominal wall. The usual procedure is that generally known as inguinal colotomy, in which some portion of the sigmoid colon is used to form the artificial anus. The transverse colon or cæcum may be used in certain special cases, however, and the site of the opening will then vary accordingly.

Colotomy is now performed in the following circumstances: (1) To relieve obstruction; (2) As a preliminary to excision of the rectum in some cases;

Fig. 12.—Diagram to show method of performing colotomy with a rod or clip.

Fig. 13.—Diagram of colotomy, with a Paul's tube tied into the upper end of the bowel. Method used when bowel has to be opened at once.

(3) To deflect the fæcal current in cases of severe and intractable ulceration of the lower bowel; (4) To relieve pain and discomfort in cancer, more especially in epithelioma of the anus.

THE OPERATION.—With the usual antiseptic precautions an incision about three inches long is made in the left inguinal region, the centre of the incision being about half-way between the umbilicus and the left anterior superior spine of the ilium. A very good incision also is a longitudinal one over the middle and outer thirds of the left rectus muscle. The fibres of this muscle are split and not divided. Contraction of the rectus muscle will subsequently give the patient a considerable amount of control over the opening. The muscles are split in the line of their fibres, and the peritoneum is opened. A loop of sigmoid flexure is then sought for and pulled out through the incision. If difficulty is experienced in finding the sigmoid flexure, the parietal peritoneum should be traced outwards with the fingers until the bowel is found. The sigmoid flexure must be pulled out until the highest portion which can be made to reach the incision is found, and this should be used to form the spur, the rest being returned. A piece of glass rod or a clip is then pushed through the mesentery just beneath the bowel (*Fig. 12*), so that the ends of the rod will rest upon the skin on each side of the incision, and support the loop or knuckle of bowel outside

the abdomen. Each end of the incision should then be partly closed by a stitch, which should also take up one of the longitudinal muscle-bands on the bowel. The object of this stitch is to close in the triangular opening at each end of the wound, and at the same time, by anchoring the bowel, to prevent prolapse of more bowel through the opening.

The operation is now complete, and a small piece of sterilized protective or rubber sheeting should be placed over the projecting bowel, and the whole covered with the usual dressings. If it is necessary to open the bowel at the time of the operation, a Paul's glass tube (*Fig. 13*) should be tied into the projecting loop of bowel.

After-treatment.—At the end of twenty-four to forty-eight hours after the operation a cut should be made transversely into the bowel with a pair of scissors. If there is any bleeding it should be stopped by pressure. At the end of eight to ten days one blade of a pair of scissors should be passed along the hole in which the glass rod is lying, and the bowel cut completely in half, so as to release the rod; any projecting bowel can also be trimmed off. The gut is quite insensitive, and no anæsthetic is required.

RESULTS OF COLOTOMY.—In old days a colotomy opening was often a source of much distress and discomfort to the patient. Now, with a good colotomy opening, the patient has practically no inconvenience whatever, and can keep himself as clean as if the bowels acted in the ordinary way. One of the writer's patients played football all one winter without the colotomy opening causing him any trouble.

J. P. Lockhart Mummery.

COMA.—The treatment of the chief conditions which lead to coma will be found under the headings, **APOPLEXY**; **SKULL, FRACTURES OF**; **MENINGITIS**; **POISONING**; **DIABETES**; **URÆMIA**; **SUNSTROKE**, etc.

COMPRESSED-AIR ILLNESS.—(See **CAISSON DISEASE**.)

CONGENITAL DILATATION AND HYPERTROPHY OF THE COLON.—

This disease is also known as Hirschsprung's disease and idiopathic dilatation of the colon. The name here used is, however, that which best describes the condition. A good deal of uncertainty still exists as to the nature and causes of the disease, the chief symptoms of which are enormous distention of the abdomen due to dilatation of the colon, and severe and intractable constipation. The majority of cases occur among young children; but the disease is not confined to any age, and cases are met with at almost all ages. Part, or the whole, of the large intestine may be involved, and the affected bowel is found to be enormously dilated, and its wall much hypertrophied. The diagnosis may be established by examination with the sigmoidoscope and by *x*-ray examinations after bismuth enemata or a bismuth meal.

Non-operative treatment is confined to attempts to get the bowels to act with regularity, and is generally only effective for a short period. The only treatment which appears to have resulted in a cure has been an operative one, and the best results have followed complete resection of the entire portion of bowel involved. The operation is of a severe character, for not only does it necessitate the removal of a considerable length of the large bowel, but as this bowel is enormously dilated and its mesentery consequently shortened, the operation may be one of the greatest difficulty. The writer has had one very successful result from appendicostomy, which, by allowing the large sacculated colon to be regularly washed out, prevented accumulation in the distended sac. Colotomy is an operation which should never be performed in these cases. The mortality from it has been considerable, as the large dilated muscular bowel

almost always tears away from the abdominal wall, and the patient dies from acute peritonitis.

For further particulars of this curious disease the reader is referred to the author's book, *Diseases of the Colon*.

J. P. Lockhart Mummery.

CONGENITAL DISLOCATION OF THE HIP.—Since Lorenz drew attention, more than a dozen years ago, to his method of reposition of the head of the femur in the acetabulum by manipulation, many surgeons all over the world have devoted much time and energy to the treatment of congenital dislocation of the hip. The condition arises either in utero, or as an obstetric injury at birth. The prognosis depends chiefly on the nature of the upper lip of the acetabulum: if this is well developed, it forms a good shelf against which the head of the femur can rest after reposition; if badly developed, the head may readily slip out again after a successful reposition.

Diagnosis of the condition is rarely made till the child begins to walk, when the waddling gait and increasing lordosis attract the attention of the mother and medical attendant. The condition ought not to be mistaken for coxa vara or any other condition of the hip, for if the surgeon lay his hand on the groin below the middle of Poupert's ligament, he should feel the femoral artery pulsating between his finger and the rounded prominence of the head of the femur. If his fingers sink into a hollow, the head of the femur is certainly not in the acetabulum. A little further investigation should suffice to distinguish the trochanter major and the head of the femur, the latter usually being displaced on the dorsum ilii. Next, with the thigh flexed at a right angle to the trunk, it is possible to get a "telescopic" movement of the limb, the head passing backwards and forwards on the dorsum ilii. In some cases this movement is not obtained, especially if a previous unsuccessful attempt at reduction has only resulted in needless injury to the soft parts and the formation of adhesions, which may greatly increase the difficulty of subsequent reposition. The recognition of this fact throws considerable responsibility on the surgeon who first attempts a manipulative reduction, for he cannot console himself with the thought that if he fails he leaves the patient no worse off than before.

The actual technique of the manipulation is now so fully described in text-books that it need not be given here in detail. Lorenz's original method is still the method in use, though of course every surgeon of wide experience acquires little tricks of manipulation peculiar to himself. Should the surgeon fail to replace the limb at the first attempt, or should he have to abandon the attempt because the shock of the pulling and stretching of the soft parts has seriously disturbed the heart's action, the patient should be put back to bed, and twenty-four hours later the limb should be extended on a double Thomas's frame in the abducted position, with counter-extension from the groin to maintain all the stretched structures in full extension. After the lapse of ten days or a fortnight to allow complete repair of the damage (note that keeping the limb in full extension prevents the formation of short adhesions; this cannot be efficiently secured by weight and pulley extension), the limb should be left free for several days at least before a second attempt is made to reduce the dislocation.

If it is found impossible to get a definite anatomical reposition, the surgeon should aim at an "anterior reposition," that is, he should get the head of the femur in front of the acetabulum well below the anterior superior spine. This is a rule which admits of no exception, because if the head is displaced posteriorly, the body weight is transmitted downwards in front of the head of the femur, and severe lumbar lordosis is produced. This not only causes an awkward gait, but the lumbar part of the spine becomes in later life the seat of severe backache, which is frequently severe enough to debar the patient from all active pursuits.

With an anterior reposition, the alteration of the line of transmission of body weight produces a natural correction of the lordosis, and averts the subsequent backache.

The functional result of a good anterior reposition is so excellent that in the best cases it is not possible to distinguish it by the patient's gait from an anatomical reposition. Further, the present writer would not undertake to distinguish by the appearances in a skiagram between a good anterior reposition and an anatomical reposition, though he may fairly claim to have a large experience of reading skiagrams. The only sure test is an anatomical one: if the head is in the acetabulum it lies behind the femoral artery below the middle of Poupart's ligament; all cases in which the head is rather external to and not directly behind the artery are anterior and not anatomical repositions. Perhaps a failure to adopt this anatomical test with sufficient strictness may explain the astonishingly high percentage of anatomical repositions claimed by some surgeons. In the hands of a competent surgeon there should be between 80 and 90 per cent of good functional results, but only something over 60 per cent of these will be in the strictest sense real anatomical repositions. Such at least is the writer's experience of over 500 cases he has had through his hands since he adopted Lorenz's method in 1902. Previous to that date he followed a modification of Paci's method, which consisted in pulling and manipulating the limb till the great trochanter was brought down to Nélaton's line, and the head near, not in, the acetabulum. A small incision was then made over the upper edge of the acetabulum, and this was chipped with a chisel with the idea of promoting the formation of a bony outgrowth and short fibrous adhesions which would keep the head more securely in place. The functional results of this method were fairly satisfactory, but not so good as with the more modern procedure. No mention need be made of open operation in connection with congenital reposition, as it is not adopted as a routine procedure by any experienced orthopaedic surgeon.

Robert Jones.

CONGENITAL PYLORIC STENOSIS.—In undertaking the management of a case of congenital pyloric stenosis, it is advisable to warn the parents at once that treatment must necessarily be prolonged, and that some weeks must elapse before any decided improvement can be looked for. The advantage of having a skilled nurse—if possible, one who has had previous experience of such cases—cannot be over-estimated.

At the outset, the propriety of surgical treatment (gastro-enterostomy, pyloroplasty, etc.) will always have to be considered. Opinion on this point is sharply divided, but the writer considers operation unnecessary in the majority of cases. The cases in which it is most indicated are those in which the symptoms are severe and have set in very soon after birth. Even in these cases, however, medical measures should be tried first, and if no improvement results in three weeks or so, the question of operation can be re-considered. From the writer's own experience, however, he feels justified in advising that even in such circumstances operation should rarely be recommended, although it must be admitted that many physicians having large acquaintance with the disease do not agree with him.

The medical treatment may be considered under the heads of (1) Feeding; (2) Lavage of the stomach; (3) Accessory measures; (4) Drugs.

1. Feeding.—If the child be still on the breast, an attempt may be made to utilize the mother's milk by drawing it off with a breast pump and administering it by means of a spoon. Usually, however, such a course results in the cessation of secretion by the breasts. Should this happen, or should the child have already been weaned (as is usually the case), an easily-digested artificial mixture

must be used. Thoroughly peptonized milk diluted with two or three times its bulk of water does very well, and may be prepared by means of Fairchild's peptogenic milk powder (e.g., 6 or 8 oz. of milk to 14 or 12 oz. of water, with the addition of one measure of the powder, and peptonized for 40 minutes). No cream should be added. A desiccated milk (such as glaxo) given very dilute may also be used, or a mixture of whey and albumin or whey and albulaetin may be substituted. Whatever the mixture selected, it should be given with a teaspoon in small feeds frequently. The exact amount which can safely be given varies, and one must feel one's way, being guided by the quantity which can be retained without exciting vomiting; an ounce or even half-an-ounce at a time will be enough to start with, and this should be given every hour. As the vomiting subsides, the amount of the feed and the intervals between feeds may be increased. After a feed has been given, the child should be kept lying on its back and be moved as little as possible. As time goes on, the nutritive value of the feeds may be increased by the addition of sugar of milk or somatose in small quantities.

2. Lavage of the Stomach should be carried out once or even twice a day through a full-sized red-rubber catheter connected with a funnel. Plain warm water may be used, and the washing should be continued until the fluid comes away clean. This may be carried out at any period of the day that is convenient, and after the washing it is well to leave the stomach empty for a time. As the vomiting subsides, the frequency of the washing may be reduced to once a day or to every other day, but if the vomiting recur it must be carried out more frequently again. It is often necessary to continue the washing for several weeks.

3. Accessory Measures.—Great care should be taken to keep the infant very warm, and it should be dressed and undressed as little as possible. If very little food can be taken, small saline enemata (2 or 3 oz. of normal saline) should be given twice or thrice a day if they can be retained. Warm fomentations to the abdomen are often helpful in allaying restlessness.

4. Drugs.—No drug is of any real value except perhaps opium, which may be given in minute doses ($\frac{1}{30}$ min. of the tincture before each feed). If it does nothing else, it often helps to keep the child quiet, but even in such small doses toxic effects must be watched for. Constipation is best treated by small enemata or by the use of soap suppositories, but occasionally it may call for the administration of a simple laxative such as castor oil or phenolphthalein (gr. $\frac{1}{2}$ to $\frac{3}{4}$).

Treatment on the above lines must be carried out perseveringly, and one must not be discouraged if, even after the lapse of several weeks, there is still no gain in weight. One should be satisfied if the child is holding its own; the rise in weight will often come quite suddenly.

Robert Hutchison.

CONGENITAL PYLORIC STENOSIS (Surgical Treatment).—If in spite of medical treatment weight is steadily lost and the quantity of curd returned shows no diminution, operation should be undertaken. This should be either Nicoll's operation or gastrotomy. The former is carried out as follows: a V-shaped incision is made in the pylorus down to the mucosa; the pylorus is then forcibly stretched by forceps introduced through a separate incision in the stomach wall, and the pyloric incision sewn up in a Y-shaped manner. No relapse has followed this operation. It is a more difficult procedure than posterior gastrotomy, but is in my opinion the wiser operation.

James Sherren.

CONGENITAL TORTICOLLIS.—(See TORTICOLLIS, CONGENITAL.)

CONGESTION, PULMONARY, and ŒDEMA.—Passive congestion and œdema of the lungs are associated especially with the cardiac failure of chronic bronchitis and emphysema, chronic heart disease or renal disease, etc., and are usually accompanied by the general signs of cardiac failure, e.g., cyanosis, dyspnœa, scanty urine, œdema of the legs, body, etc. Often it appears to be the beginning of the actual process of death.

The treatment is largely dependent upon the condition with which it is associated. In most cases there is urgent need for active intervention in order to relieve the overworked heart; sometimes, however, the œdema develops in association with profound anæmia or cachexia, parenchymatous nephritis, cerebral disease, toxæmias, etc., and there is no evidence that it is caused or even aggravated by mechanical difficulties. In this second group the œdema is almost always a sign of impending dissolution, and treatment is seldom of avail.

The indications for treatment will depend almost entirely on the causative condition. In the first group, if the mechanical difficulties can be diminished and the heart stimulated, treatment may often have a very satisfactory result.

In the most serious cases, with cyanosis and engorgement of the veins and right side of the heart, venesection often gives prompt relief; 15 to 20 oz. of blood should be withdrawn from the median basilic vein. Unfortunately, there is a prejudice on the part of the general public against the treatment, and if it is not successful the practitioner may incur undeserved blame. It can, however, be confidently asserted that in many cases no other form of treatment is so likely to meet with success. In less serious cases blood may be abstracted by leeches, and bleeding from the leech-bites may be encouraged by the subsequent application of fomentations. Dry cupping is sometimes employed, but compared with bleeding or leeching is a very inefficient method for securing venous depletion.

The posture of the patient should receive careful consideration; a comfortable easy chair with a support in front on which the patient may lean is often preferable to a bed. When sitting, the patient can breathe more easily, and the support to the arms permits the action of the accessory muscles of respiration. Moreover, gravity allows the blood to accumulate in the portal area, so that the distention of the right side of the heart is relieved and the œdematous fluid collects in the legs, where it causes less mechanical trouble. A patient with passively congested lungs may often be coaxed to sleep in a chair, though insomnia troubles him while he remains in bed. A chair specially adapted to the purpose is in use at the London Hospital. Œdema of the lungs is often associated with effusions into the pleura or peritoneum, and with œdema of the dependent parts; collections of fluid in the pleura or peritoneum should be removed slowly by paracentesis.

If there is great œdema of the legs without renal disease, it is often advisable to allow the fluid to escape either by multiple small punctures through the skin or by the insertion of Southey's tubes, the strictest aseptic precautions being observed. When there is renal disease, the risk of sepsis following puncture is so great that the operation is seldom advisable.

In some cases of pulmonary œdema with cyanosis the inhalation of oxygen is of value; the gas delivered direct from the cylinder is very cold owing to the sudden expansion; it is also very dry; to mitigate these disadvantages, it is wise either to fill a bag with the gas and allow it to remain in the room for some time before administration, or to pass the gas through a tube coiled in a can of hot water, or to allow it to bubble through hot water in a bottle arranged for the purpose with two tubes through the cork, the supply tube passing well below the surface of the water. The effect of the administration of oxygen should be

carefully watched, and continued only if relief is obvious. It is best to keep the cylinder and any cumbrous apparatus out of the patient's sight.

The use of drugs in the treatment of pulmonary congestion and œdema depends almost entirely on the etiology of the condition. Roughly they may be grouped into those which are used as whips to thrash the tired heart into increased effort, those which are true cardiac tonics augmenting the muscular tone, and those which aid the heart's action by diminishing the resistance which it has to overcome. Many drugs, however, may be included in more than one of the above groups.

Of the cardiac whips, ammonia, ether, strychnine, and caffeine are the most commonly employed:—

R Spiritus Ammonia Aromatici	Aquæ Camphoræ	q.s. ad ʒj
Spiritus Ætheris	aa ℥xxx	
	Occasionally.	

Or,

R Injectionis Hypodermicæ Strychninæ Hydrochloridi 1% ℥ij-iv (i.e., gr $\frac{1}{10}$ — $\frac{1}{20}$)
Every four hours if necessary.

Or,

R Caffeinæ Sodio-Salicylatis gr ij-v
To be given as an intramuscular injection occasionally, or if necessary every four hours.

Of the cardiac tonics, digitalis, strophanthus, and convallaria are the most frequently employed. The effect as a rule is not noticeable until thirty-six to forty-eight hours after the commencement of administration.

R Tincturæ Digitalis	℥xx	Potassii Acetatis	gr x
Infusi Digitalis	ʒj	Aquæ Chloroformi	q.s. ad ʒj
	Every three or four hours.		

Or Merck's or Nativelle's granules of digitalin (containing $\frac{1}{4}$ mgm of digitoxin) may be given thrice daily for not more than a week at a time.

In prescribing digitalis, it must be remembered that it is cumulative in action, that it constricts the peripheral arterioles, and often acts as a gastric irritant, causing vomiting. Strophanthus to a large extent is free from these defects, but unfortunately is a very uncertain drug;* it should be tried if digitalis cause vomiting, if the vessels be degenerate, or the aortic valves incompetent.

R Tincturæ Strophanthi	℥iiss	Syrupi Aurantii	ʒss
Extracti Convallariæ Fluidi	℥viij	Aquæ	q.s. ad ʒj
Tincturæ Cardamomi Co.	ʒss		
	Every four hours.		

The third group consists of drugs which reduce the work of the heart in various ways; some act as vasodilators, e.g., amyl nitrite, liquor trinitrini, sodium nitrite, erythroltetranitrate, etc.; others, like mercury or aperients, by withdrawing fluid from the blood; yet again others in a manner as yet undecided, e.g., the iodides, alcohol, etc. These drugs are seldom prescribed alone; in fact, drugs from all three groups are frequently combined with advantage:—

R Tincturæ Digitalis	℥xij	Spiritus Ammonia Aromatici	ʒss
Infusi Digitalis	ʒss	Aquæ Camphoræ	ad ʒj
Potassii Iodidi	gr iv		

Every four hours, the effect on the pulse being carefully watched.

Or,

R Pulveris Digitalis Foliorum	Massæ Hydrargyri	aa gr j
Pulveris Scillæ		
	Ft. pil. Twice daily.	

Saline aperients and mercurial purges are often of great value, and are best given separately, e.g., a grain of calomel may be given at night, to be followed

* Hatcher's studies have convinced the American Editor that strophanthus and strophanthin (ouabain) should not be given by mouth.

in the morning by a dose of magnesium or sodium sulphate, Carlsbad salts, Hunyadi, Friedrichshall, Apenta, or the like.

The value of alcohol in pulmonary œdema is generally doubtful; it seems to act best when there is pyrexia. A good rule is to try a small dose of good old brandy or malt whisky containing plenty of ethers, and be guided by the result; if the benefit be not soon obvious, it is useless, and possibly harmful, to repeat the dose.

Diaphoretics are occasionally recommended in the treatment of pulmonary œdema: it is best to avoid their use. Occasionally they may be actually dangerous; for instance, pilocarpine may lead to a great increase of the bronchial secretion, and hot-air baths usually prove very exhausting to the patient.

Sleep is of supreme importance; the measures that may be adopted in the attempt to secure it are those which have been discussed in connection with BRONCHITIS, CHRONIC.

Cecil Wall.

CONJUNCTIVA, DISEASES OF.

Conjunctivitis.—The essentials in the treatment of all conjunctivitis consist in (1) Ridding the conjunctiva of any specific germ, if present; (2) Washing away the discharge and preventing its collection behind the closed lids; (3) Keeping a careful watch on the cornea; (4) Maintaining the health of the patient.

The chief danger in conjunctivitis is the implication in one way or another of the cornea—either by ulceration, which may go on to perforation and loss of the eye, or by cutting off the blood-supply by intense swelling of ocular conjunctiva and episcleral tissue, supplemented by pressure of the swollen lids, which may lead to degeneration and even sloughing of the whole cornea.

Hence, in every case of conjunctivitis, the cornea must be thoroughly examined at the first visit, and a careful watch kept that the earliest sign of impairment be detected, from the point of view both of treatment and prognosis. In any case of doubtful nature, smear-preparations of the discharge should be taken for microscopic examination, or a swab sent for laboratory investigation.

In examining the cornea, great care must be taken not to press on the lid, lest the surgeon himself cause the perforation of an ulcer which has already nearly penetrated. The skin of the lid should be dried and the lid lifted with the thumb placed lightly close to the ciliary margin. If this is impracticable from the amount of swelling, a lid retractor may be used; or if the patient is refractory and there is much blepharospasm, an anæsthetic must be given. (In using the retractor care should be taken not to touch the cornea with the instrument, lest an abrasion be caused, which may be the starting-point of an ulcer. If a retractor is not at hand, the loop end of a sterilized hairpin bent round makes a handy and useful instrument.)

Applications are made to the conjunctiva of varying strengths, suitable to the nature of the inflammation, combined with frequent irrigations with some bland solution, to wash away the discharge. The lid margins are moistened with ointment to prevent their sticking together, and to allow the discharge to escape. *No bandage should be used*, but the eyes are protected by a shade,* or dark glasses. If the discharge is profuse, and the lids are so swollen that they cannot be everted, the external canthus must be divided to allow applications being made right up to the fornix. This is easily done with one snip of a strong pair of sharp scissors, of which one blade is passed into the conjunctival sac, the other being outside. The cut is made straight through, from skin to conjunctiva,

*A shade made of brown paper with a tape run through near the upper border is useful, and can be changed at once on getting soiled.

in the line of the external palpebral ligament. The resulting scar soon becomes quite invisible.

If corneal ulceration occurs, atropine is given, and our treatment of the conjunctiva must be still more assiduous. If necrosis of the cornea sets in, eserine, 2 gr. to the ounce, may be given as a corneal stimulant, and if there is much chemosis, and the swollen lids are pressing unduly and impeding the circulation, division of the external canthus is also called for.

Tonics are ordered if necessary, and plenty of fresh air is ensured. Even in the milder cases, close work of all kinds is prohibited, and the patient is told to avoid all dust and smoke.

To prevent the spread of the infectious forms of conjunctivitis, strict injunctions must be given that no one but the patient use his towel, sponge, etc., and that such articles, and handkerchiefs, be carefully disinfected.

In the severe forms of infective conjunctivitis, where one eye alone is attacked, the other must be protected at once by a glass shield (Buller's shield).

Nitrate of Silver.—Of the various silver salts used for painting the lids, silver nitrate is the most efficacious in cases of severe conjunctivitis associated with purulent discharge. Protargol and argyrol cause less pain, but their curative effects are not so thorough.

A few hints as to the method of applying silver nitrate may be of value :—

1. A stronger solution than 2 per cent should not be used. One light application of this strength is generally sufficient, but if a greater effect is desirable, any degree of cauterization can be obtained by mopping the conjunctiva after the first application and painting again, and so on, till the required effect is produced. With the stronger solutions, too great an effect may be obtained at the first application. After using the 2 per cent solution, it is not essential to neutralize with salt solution. The excess should be mopped up, keeping it as much as possible from the cornea, and the eyes should then be bathed with boracic lotion.

2. The stick of pure nitrate of silver should *never* be used in conjunctivitis.

3. When the discharge is profuse, the eyes should be painted once a day ; in very exceptional cases twice a day, but never more frequently. *A second application should never be made till the slough produced by the preceding painting has come away.*

4. Silver nitrate should never be used (a) in membranous conjunctivitis, when the membrane is adherent and cannot easily be wiped off ; (b) When there is brawny infiltration of the lid, lest the caustic produce a deep necrosis of the tissues of the lid.

5. As the discharge diminishes, the applications must be correspondingly less frequent, and when it has ceased, painting must not be made more than once or twice a week, the conjunctiva being brought back to its normal condition with zinc chloride (1 gr. to the ounce), zinc sulphate (2 gr. to the ounce), or copper sulphate (1 or 2 gr. to the ounce).

6. The best way of applying the solution is with a cotton-wool mop, made by twisting a little wool round the drawn-out end of a small glass rod. Be sure that the end of the rod is quite smooth and rounded. The projecting portion of wool makes a soft brush, which can easily be removed and renewed. A fresh one is used for each eye. (A camel's-hair brush is not so aseptic, and the quill is apt to scratch the cornea when painting out the fornix, so important in gonorrhœal conjunctivitis.)

The effects of too frequent or too strong applications of silver are sloughing of the lids, and a grey-white opacity or even destruction of the cornea. Too prolonged use of silver causes permanent greyish or brown staining of the conjunctiva.

Gonorrhœal Conjunctivitis and Ophthalmia Neonatorum.—Though many cases of ophthalmia neonatorum are not due to gonococcal infection, the treatment is identical in the two cases.

Every man or woman with gonorrhœa should be warned of the risk of acquiring conjunctivitis, and in order to avoid this, be instructed how to maintain the necessary cleanliness (e.g., by not washing the face in the bath, using a special face towel, care with regard to the sponge, etc.), since this disease in adults often runs a very serious course, and may lead to the loss of one or both eyes, even in spite of treatment. Also those attending to these cases must realize the importance of absolute cleanliness, and of disinfecting or destroying everything that has come in contact with the discharge.

In ophthalmia neonatorum, prevention is better than cure. (1) The baby's face and lids should be carefully wiped directly the head is on the perineum; (2) After the child is born the eyes should be well washed with a sublimate solution, 1-4000; (3) If there is any suspicion that the case is not a clean one, a drop of a 2 per cent solution of silver nitrate should be dropped into each eye in addition to the above treatment; (4) At the baby's first bath, the face should not be washed in the same water that has washed its body; (5) As soon as there is any sign of inflammation, treatment should be begun forthwith.

Constitutional Treatment.—This is very important, and in the case of adults the general health must be maintained with generous diet, tonics and stimulants if necessary, and the depressing influence of the disease as far as possible alleviated.

Local Treatment.—If one eye only is affected, the other should at once be protected with a Buller's shield, great care being taken in adjusting it, so that the plaster be made to adhere very firmly down the nose. The chief danger of the complaint being ulceration and perforation of the cornea, a thorough examination must be made at the first visit (see above, CONJUNCTIVITIS), and also later from time to time.

In the first stage (infiltration), when there is brawny infiltration of the lids, or membrane adherent to the conjunctiva, *silver nitrate must not be used*, but instead rounds of lint soaked in a cold boric solution placed over the eyes and frequently changed, combined with frequent irrigation* with mild antiseptics, such as boric lotion, or sublimate solution, 1-10,000. In adults, leeches may be applied to the temples if there is much pain.

As soon as the second stage is reached, the discharge thoroughly established, and the brawny condition of the lids has subsided, painting with 2 per cent solution of nitrate of silver must be begun, combined with very frequent irrigation. The painting should be done once a day, or, where the discharge is very profuse, twice a day. A second application must not be made until the slough produced by the preceding painting has come away. The wool swab should be introduced right up to the fornix, great care being taken not to injure the cornea either with swab or finger-nail. If there is so much swelling of the lid that painting cannot be carried out, and the discharge cannot get away, the external canthus should be divided (see above). The irrigation with sublimate solution, 1-10,000, should be carried out every hour during the day, and every two hours during the night, with swabs of wool soaked in the lotion, or with the "undine." All discharge is scrupulously washed away, and the lid margins are moistened with ointment to prevent sticking.

As soon as the discharge has ceased, painting must be stopped and replaced

* A useful plan, if complete nursing is not available, is for the patient to have a bowl of cold lotion with rounds of lint soaking in it placed on the right side of the bed, and an empty bowl on the left side. A cool round is taken from the right bowl, applied to the eye and, as soon as it is warm, placed in the left bowl and replaced by a fresh one.

by astringent drops (e.g., zinc chloride, 1 gr. to the ounce), or the application of the copper sulphate stick.

Complications.—1. Corneal ulceration. Silver is not contra-indicated, but neither zinc sulphate or chloride, nor copper sulphate should be used. Atropine ointment, 4 gr. to the ounce, should be inserted between the lids twice a day, and still greater care must be used in manipulation, to prevent perforation. While there is purulent discharge, even if there is infiltration of the ulcer, perforation, or prolapse of the iris, nothing in the way of operation can be done until the conjunctival sac is clean. (For later treatment see CORNEA, DISEASES OF.)

2. If there is intense swelling of the lids and conjunctiva, and the cornea becomes grey and hazy from the cutting off of its blood-supply, the external canthus should be divided to relieve pressure, and eserine drops, 2 gr. to the ounce, instilled twice a day to try to improve the nourishment of the cornea. (See also GONORRHOEA.)

Acute Catarrhal Conjunctivitis.—The most severe cases of acute catarrhal conjunctivitis should be treated in the same way as gonorrhœal cases (q.v.). In the milder forms, it is not necessary to keep patients in bed; they are better for being up and getting all possible fresh air, the eyes being protected with dark glasses and a shade. The conjunctiva should be painted once a day with 2 per cent silver nitrate or 30 per cent protargol so long as the discharge is profuse, and the conjunctival sac be washed out four times a day (more often if the discharge is very profuse) with boric acid lotion or a sublimate solution, 1-10,000, boracic ointment being smeared along the edges of the lids, especially at bed-time.

When the discharge has ceased, chloride of zinc drops, 1 gr. to the ounce, should be used three times a day, and the silver discontinued.

If ulceration of the cornea occur in the acute stage, atropine ointment, 4 gr. to the ounce, should be inserted between the lids, in sufficient quantity to keep the pupil well dilated. Ulceration is no indication to stop the use of silver, but the ulcer itself should be painted only if it is infiltrated, and then very lightly. The cornea should be carefully protected from the silver if necrosis is threatening.* While there is discharge a bandage must not be used even if ulceration be present. Cauterization with actual cautery or pure carbolic is of no use in the presence of septic discharge, but if the ulcer remain infiltrated after the discharge has ceased cauterization may be of great service. (See CORNEA, DISEASES OF.)

Chronic Catarrhal Conjunctivitis.—In all forms of chronic inflammation of the conjunctiva the refraction should be tested as a routine measure, and the correcting glass worn constantly. It is striking how even cases due to trachoma improve if the refractive error be corrected. The general health of the patient should be attended to, and avoidance of dust and smoke enjoined.

Locally, if there be discharge, lightly painting with 1 per cent silver nitrate solution, or 30 per cent solution of protargol, is useful. If small yellowish-white concretions are seen in the conjunctiva, these should be picked out with a needle, after anæsthetizing with cocaine and instilling a drop of adrenalin. Astringent lotions, such as zinc sulphate (1 or 2 gr. to the ounce), zinc chloride (1 gr. to the ounce), weak alum, or tannin solution also are of service; these should be used three times a day, but not the last thing at night. Before going to bed a mild ointment of boracic acid, or yellow oxide of mercury, $\frac{1}{2}$ per cent, may be smeared along the edges of the closed lids to prevent their sticking.

In *angular conjunctivitis*, zinc sulphate, 2 gr. to the ounce, is generally the

* Necrosis is recognized by a diffuse greyish-yellow infiltration of the whole cornea.

most useful lotion, but this often acts better when combined with occasional painting with protargol or nitrate of silver.

Follicular Conjunctivitis.—The recognition that the conjunctival condition is only a local manifestation of a general tendency to lymphatic overgrowth, shown elsewhere by adenoids, large tonsils, etc., is of the first importance in successful treatment. Fresh air, good simple food, and tonics, especially iron and cod-liver oil, are indicated. The refraction should be carefully tested, and the correcting glasses worn regularly (especially in cases of hypermetropia and astigmatism). Locally, zinc chloride, 1 gr. to the ounce, is found most useful in the chronic condition, while if there is discharge, painting with protargol or silver twice a week is advisable till this ceases. If the granulations are very large, expression is often most useful. (See TRACHOMA.)

Follicular enlargement is often found associated with the more acute inflammations of the conjunctiva, especially acute catarrhal conjunctivitis. The combination of these two conditions at times may closely simulate trachoma. The importance of making a correct diagnosis cannot be over-estimated.

Phlyctenular Conjunctivitis.—(See CORNEA, DISEASES OF.)

Membranous and Diphtheritic Conjunctivitis.—Membranes on the lids are met with fairly commonly in severe conjunctivitis, apart from diphtheria, and cases can be divided conveniently into two groups:—

1. *Those in which the Membranes can easily be wiped off without leaving a Bleeding Surface.*—These should be treated as cases of acute catarrhal conjunctivitis (q.v.), but till the membrane disappears, solutions of nitrate of silver must be used sparingly, and if fresh membranes form which remain adherent, it must be altogether withheld.

2. *Those in which a tough Membrane is adherent, and if pulled off leaves a Bleeding Surface.*—These should be treated as diphtheritic till the result of bacteriological examination is known—a procedure of the utmost importance, both in making a correct diagnosis and in the after-treatment.

The patient must be isolated, and precautions against the spread of infection taken. As in other forms of diphtheria, antitoxin is our first line of defence; and since the disease is usually very severe, the cornea becoming rapidly and irredeemably affected, when diphtheria is suspected antitoxin should be injected without delay.

General Treatment is the same as in diphtheria elsewhere. The patient's health must be kept up with plenty of food, stimulants being given if necessary. Rest in bed is essential. The heart must be regularly examined, and great care taken to avoid cardiac failure.

Locally, the chief danger being ulceration or necrosis of both cornea and lids, we have to maintain as far as possible the circulation in the conjunctiva, episcleral tissue, and lids, and our manipulations must be as gentle as possible. If only one eye is affected, the sound one must be protected by a Buller's shield.

In the first stage, when the lids are brawny and tense, several layers of hot boracic lint are laid over the eyes and frequently changed: these are kept in position if necessary by means of a bandage round the forehead, but not over the eyes. The discharge is washed away by frequent irrigation of the conjunctival sac with some bland fluid, such as boracic lotion, by means of an "undine" or swabs of wool. No silver nitrate or any caustic must ever be used in this stage. If the lids cannot be easily everted they should not be forced open beyond the degree necessary to make a diagnosis and allow the discharge to come away freely. When the second stage has been reached, and the lids have become soft, the membrane has come away, and the discharge is free, a 2 per cent solution of silver nitrate may be used once a day for painting the lids so long as the discharge lasts (see above, CONJUNCTIVITIS).

When antitoxin cannot be secured, quinine lotion (sulphate of quinine, 4 gr. to the ounce, dissolved with the smallest possible quantity of dilute sulphuric acid) should be used to irrigate the conjunctival sac, four times a day.

Even when the cornea is affected, little more can be done. In the case of ulceration, we must be still more gentle in our manipulations, and atropine ointment should be inserted between the lids twice a day. Where the cornea becomes grey without ulceration, and necrosis is threatening, some prefer eserine ointment, 2 gr. to the ounce.

If in the treatment of severe cases the lids tend to become adherent to the ocular conjunctiva (symblepharon), the two must be kept apart during the healing process by daily passing a glass rod round as far as the fornix, and oily applications should be used, such as atropine ointment.

Trachoma.—The contagious nature of this serious disease is not, as a rule, sufficiently realized either by the patient or his friends. Warning on this point, therefore, should be impressive, considering the pain and discomfort the disease causes, its long duration, and its menace to sight. Towels, handkerchiefs, sponges, and flannels should be rigidly kept for the patient alone. Few cases, if treated regularly, get well in less than six months: many, owing to neglect, last a lifetime; hence perseverance on the part of both doctor and patients is an all-important factor in successful treatment.

The chief dangers of the disease are:—

1. Pannus and ulceration of the cornea, leading to opacities and consequent impairment of sight.

2. Scarring of the lids, leading to entropion and trichiasis (which latter again leads to more ulceration and opacity of the cornea).

3. Shrinking and xerosis of the conjunctiva.

These are late signs, and occur when the disease has lasted many months: our object must, therefore, be to get the disease under control before they have occurred. The treatment of these conditions will be mentioned later.

The health of the patient should be well maintained. The eyes should be protected from glare, dust, and wind with large tinted glasses, and as in all cases of chronic inflammation of eyes and lids, the refraction should be tested when possible, and if there is any error, the correcting lenses in neutral tint should be worn.

Acute Cases.—Occasionally in the early stages there is a considerable amount of swelling of conjunctiva and lids; sedative treatment should then be adopted, e.g., hot boracic bathing four or five times a day, and mild applications of silver nitrate solution, 5 gr. to the ounce, once a day. But when the acute symptoms have subsided, the conjunctiva must be vigorously treated with astringents.

Chronic Cases.—1. Where florid granulations exist, these should be expressed with either Grady's or Knapp's forceps. This is a very valuable but painful procedure, and should be carried out either after thoroughly cocainizing the conjunctiva with powdered cocaine, or under a general anæsthetic, preferably the latter. After everting the lids, all the granulations are thoroughly broken down and removed by squeezing between the forceps. (The eyes of both surgeon and assistants should be protected by glasses during expression, to prevent contagion.) After expression, soothing applications may be made for a day or two, followed by energetic astringent treatment.

2. When the conjunctiva is velvety, and there are no granulations (or any existing granulations have been expressed), regular painting must be carried out three times a week, or in severe cases every day, either with a 2 per cent solution of nitrate of silver, the copper stick, or a 2 per cent solution of perchloride of mercury in glycerin—the latter is painful but is often very efficacious. In addition the patient has his conjunctival sac well washed out with boric

lotion or sublimate solution, 1-8000, four times a day, and the edges of the lids smeared with boracic ointment, 1 dr. to the ounce, at night, to prevent the lids sticking together. At this stage the application of carbon dioxide snow is efficacious, but painful.

3. When scarring has begun, daily application of the copper stick is by far the best remedy, and this should be continued till all traces of hypertrophy of the conjunctiva have disappeared. Where such frequent applications of copper either cannot be made or are unnecessary, the patient may use copper sulphate drops, 2 gr. to the ounce, twice a day, in addition to the sublimate lotion.

Pannus usually gets well with the above treatment of the lids; when it is severe, atropine should be given, either by itself as drops or ointment, or in combination with the copper drops. If it persist, it may need special treatment with jequirity, the jequiritol serum, x rays, or peritomy.

Ulceration of the Cornea must be treated on ordinary lines. (See CORNEA, DISEASES OF.) Atropine should be given, but neither the copper stick nor the solution of sublimate in glycerin should be used. Nitrate of silver, on the other hand, is not contra-indicated.

For treatment of entropion and trichiasis, see EYELIDS, DISEASES OF.

For shrinking and xerosis of the conjunctiva little or nothing can be done beyond trying to relieve the patient by bland oily or mucilaginous applications, such as paraffinum liquidum.

Spring Catarrh.—Treatment in this condition has in the past been of little avail, but recently some good results have been obtained by means of x rays and radium. Apart from these most good is obtained by the use of dark glasses, and of mild astringent lotions combined with adrenalin, e.g., boracic acid 10 gr., zinc sulphate $\frac{1}{2}$ to 1 gr., adrenalin solution (1-1000) 1 to 2 dr., water to the ounce.

Xerosis of the Conjunctiva.—

1. Little can be done for those cases associated with severe disease of the conjunctiva (trachoma, pemphigus, etc.), beyond giving oily or mucilaginous preparations.

2. Cases of xerosis associated with degeneration of the cornea (keratomalacia) in marasmic children chiefly need treatment for the general condition, and locally, hot applications to improve the nourishment of the cornea, boracic bathing, and eserine drops, 2 gr. to the ounce.

3. Cases in which neither conjunctiva nor cornea is severely affected need only general feeding up, fresh air, attention to the digestion, and maltine and cod-liver oil.

Burns and Scalds of the Conjunctiva (Caustics, etc.).—The chief dangers are ulceration, sloughing of the cornea, and symblepharon.

The conjunctival sac must be washed free from all irritating substances. Great gentleness should be exercised, only warm bland fluids such as boracic or normal saline lotions being used, both for this and for washing away the discharge. If *acid* has burnt the eye, a solution of sodium bicarbonate, 5 gr. to the ounce, is useful at the first washing, to neutralize it.

The eye must be kept scrupulously clean, and the discharge prevented from collecting behind the lids by frequent irrigation. If the cornea is in danger from pressure of the lids on the swollen conjunctiva, or if the eye cannot be kept properly clean owing to tense swelling of the lids, the external canthus should be divided. Rounds of lint, which have been soaked in hot boracic lotion, just laid over the eyes, are very comforting. In severe cases the patient should be kept in bed.

If there is any ulceration of the cornea, iritis, or cyclitis, atropine ointment, 2 or 4 gr. to the ounce, should be used, sufficient to keep the pupil well dilated.

If the cornea is in danger of sloughing, eserine ointment, 2 gr. to the ounce, may be tried. If the opposing surfaces of palpebral and ocular conjunctiva are ulcerated, adhesions (symblepharon) are very liable to occur. These must be prevented by passing round daily a smooth-ended glass rod right into the fornix, and by using oily non-irritating applications, e.g., atropine ointment, when atropine is indicated by the presence of corneal ulceration, or pure soft vaseline. (Boracic ointment is almost always irritating to the conjunctiva.)

Tumours of the Conjunctiva.—*Dermoid Tumours* are excised, the conjunctiva being brought together as far as possible over the resulting wound.

Papillomata and *Polypi* are snipped off right to their base; this is then cauterized with either the platinum loop or a sharply pointed stick of nitrate of silver.

Granulations are treated in a similar manner, and if associated with a chalazion which has ruptured, the latter must, of course, be scraped out at the same time.

Epithelioma and *Sarcoma* are very rarely met with, but must be removed thoroughly, allowing a wide margin, or if too extensive for local removal, the eye must be sacrificed.

W. Tindall Lister.

CONSTIPATION IN CHILDREN.—In infants, even when at the breast, constipation is a common trouble. It may be due to deficiency of sugar or fat in the milk, to excess of proteins, or to improper feeding generally, which burdens the alimentary canal with a large and undigested residue, and excites a mild catarrh of the bowels. Regulation of the diet should, therefore, be the first step in the treatment. A nursing mother should be instructed not to put her child to the breast too often, or to quiet it by that means whenever it cries. With hand-fed infants, measures should be taken to prevent a too firm clotting of the curd of the cow's milk by the addition of a third part of fresh barley-water, or by adding to each ounce of the milk one or two grains of citrate of soda. Sufficient variety in the diet is to be insisted upon (see VOMITING IN CHILDHOOD), and if there be any want of sugar or fat in the food, a teaspoonful of fresh syrup or cream can be added to the bottle or given pure after the meal two or three times a day.

Costiveness may result from dryness of the stools owing to too little fluid in the food. If this be the case, the food must not be made too thick, and it is well to supplement the meals by some plain water or barley-water. This is especially necessary in warm weather when the skin is acting freely. A stint of water is often shown by diminished secretion from the kidneys and the appearance of sand in the urine. In the summer young children love water, and will drain the whole contents of a feeding-bottle if allowed to do so. Therefore, if the urine be scanty and high-coloured, and especially if sand be found on the diaper or at the bottom of the chamber pan, four or five ounces of cold water (boiled and filtered) should be allowed between meals several times a day. By this means the bowels can often be made regular in a very short time.

Any cause which is sufficient to set up a mild catarrh of the bowels will induce constipation in a young child, for the increased mucous secretion covers the faecal masses with a slimy coating, so that the muscular wall, in its contractions, slides ineffectually over their surface. For this reason short-coating an infant is often a cause of constipation. As long as the catarrh continues a cure cannot be effected; therefore attention must be paid at once to the child's clothing, his bath, and his general management, so that any error may be righted without delay.

However induced originally, constipation cannot continue long without adversely affecting the peristaltic movement of the bowels. The colon becomes accustomed to be overloaded, and its contents no longer have a stimulating

effect upon its lining membrane, so that the muscular contractions begin to flag. In badly nourished infants this sluggishness of movement is combined with actual weakness of the muscular walls; and if to this be added dilatation of the bowel from accumulated faecal matter and gas, the expulsive force left at the disposal of the patient is small indeed.

For the successful treatment of constipation in the infant this cause of sluggishness of bowel must be kept in mind, and the administration of drugs should be seconded by systematic massage of the abdomen. For this it is seldom necessary to call in the aid of a professional masseuse; an intelligent nurse will soon learn to apply firm pressure with the ball of the thumb round and round the belly in the course of the colon.

In cases where the costiveness is of considerable standing, a cure can rarely be effected without the aid of aperients, for the bowels have to be educated to provide a daily relief. If the accumulation be large it will be necessary to begin with a dose of calomel, followed after a few hours by a saline aperient; and it may be necessary to supplement the latter by a copious injection of warm water. In ordinary cases, however, watery injections are to be avoided for fear of over-dilating the bowel; it is far better to provoke an evacuation by a suppository of soap or glycerin. Afterwards, to keep up a regular action of the bowels, any mild aperient may be ordered, such as liquorice powder or cascara sagrada, and it is generally advisable to combine the laxative with small doses of nuxvomica and belladonna:—

R Fluidextracti Cascarae	$\mathfrak{M} \text{ x-xx}$	Glycerini	
Tinctura Belladonnae	$\mathfrak{M} \text{ iij-vij}$	Aquae	$\text{aa q.s. ad } \mathfrak{Zj}$
Tinctura Nucis Vomicae	$\mathfrak{M} \frac{1}{2}$		

This dose can be given every night. As children vary greatly in their response to laxative remedies, it will be necessary to find out in each case the dose required to produce a satisfactory result. This treatment must be persevered with for weeks or even months, gradually reducing the dose of the aperient as improvement advances, until it can be dispensed with altogether.

In cases where the stools are too dry and the addition of fluid to the food has not been followed by improvement, it is advisable to give a small dose of some saline aperient in the last bottle taken at night, and ten or fifteen grains of phosphate of soda, or a good tablespoonful of solution of magnesium bicarbonate (B.P.) added to the meal will be found to have a useful influence in increasing secretion from the mucous membrane. In some cases it is better to combine the saline with a tonic; thus:—

R Sodii Sulphatis	$\text{gr } \text{x}$	Acidi Sulphurici Diluti	$\mathfrak{M} \text{ j}$
Quinina Sulphatis	$\text{gr } \frac{1}{4}$	Glycerini	$\mathfrak{M} \text{ xv}$
Tinctura Nucis Vomicae	$\mathfrak{M} \frac{1}{2}$	Infusi Calumbae	$\text{q.s. ad } \mathfrak{Zj}$

To be given three times a day.

Many other drugs may be used as alternative remedies to those already mentioned, and if taken regularly may be prescribed in comparatively small doses. Thus, half a grain of sulphur, if taken every night, often has a sufficiently regulating influence upon the bowels. In young infants a small piece of manna dissolved in hot water and strained through muslin may be added to the last bottle of the evening; or a teaspoonful of olive oil may be given after the last meal. It may be here stated that the aperient syrups of commerce, sold under the name of "elixirs," if they owe their sweetness to sugar, are not fit remedies for children. The syrup of which they are composed quickly becomes stale, and, fermenting in the child's stomach and bowels, is a fruitful source of indigestion and flatulence.

In the case of children after the age of infancy, a regulation of the diet and habits of life forms an important part of the treatment. Certain articles of

food—eggs in some children, excess of starch in others—have a constipating tendency. As in the case of infants, a sufficient variety should be enjoined in the diet, and care should be taken that the child is not fed exclusively or almost entirely on starchy and saccharine matters. Mutton, fish, chicken, and green vegetables should all form part of his diet, and he should be led to eat whole-meal bread and take porridge for his breakfast two or three times a week.

In many children, both boys and girls, habitual neglect of the calls of nature induces a habit of constipation which it is not easy to overcome. Regularity in this respect is therefore to be insisted upon, and the child should be trained early to go to stool every morning as part of the daily routine. In school-girls want of exercise may be a cause of costiveness, but this is easily remedied.

To produce an immediate evacuation the same measures may be resorted to as those recommended for infants. Afterwards, if the costiveness is a habitual condition, it will be necessary to prescribe a mild laxative to be taken regularly every evening, so as to recover the habit of a daily stool. The dose must be taken just before the last meal. For this purpose two grains of the extract of cascara sagrada may be given as a pill, combined with one-sixth of a grain of extract of belladonna and one third grain of extract of nux vomica. Excessive dryness of the stools may be modified by giving an ounce or more of Apenta or other natural aperient water when the child goes to bed. In obstinate cases of the kind a useful remedy is:—

R Sodii Sulphatis	℥ss	Glycerini	℥xv
Tincturæ Belladonnæ	℥xij	Infusi Sennæ (B.P.)	
Tincturæ Nucis Vomice	℥iiss	Infusi Calumbæ	āā q.s. ad ℥ss

To be taken before food once, twice, or three times a day.

For a child of six years.

If only one dose is taken, it should be given in the evening before supper.

In some cases parents show a singular prejudice against the continued use of laxative remedies. If this be so, we may fall back upon liquid paraffin or the preparation known as "lenitol." Either of these will often be found to act sufficiently in cases of mild sluggishness of the bowels if given several times a day in doses of about one teaspoonful. They are not strictly aperient, but, like olive oil, induce a relief to the bowels by their lubricating action upon the lining membrane. They are also antiseptic, and are useful in checking fermentation in the contents of the intestine.

If the bowels have been sluggish and insufficiently relieved for weeks together, there may be a great accumulation, and ordinary aperients yield but scanty results. In such a case a good dose of castor oil will often produce an effect not attained by the most drastic purgatives. If this also fail, we may conclude that the immobility of the bowel is the consequence of spasmodic contraction of the muscular coat of the intestine. For such a condition sedative remedies which relax the spasm are of more service than irritating aperients which tend to confirm it. The best treatment is belladonna given in frequent doses until it produces wide dilatation of the pupil. Children, it must be remembered, take belladonna well. It is best to give one-quarter of a grain of the pure alcoholic extract every two hours, and as a rule, when a decided impression has been made upon the pupils, the bowels are copiously relieved.

If the accumulation have gone on to complete impaction of the bowel, it will be necessary to persevere for some time with enemas, so as to break up the fecal masses which occupy the sigmoid flexure and rectum. It is best to give first a full dose (2 to 4 gr.) of calomel, followed by castor oil, so as to produce a softening effect upon the masses, and then to use a large injection of thin, warm gruel, containing an ounce of castor oil and half an ounce of oil of turpentine. The

injection must be given very slowly, pausing frequently when the distention of the bowel causes discomfort, until this has subsided, and by this means large quantities of fluid can be introduced. A persevering use of this method will succeed in the most obstinate cases, especially if the belladonna treatment be employed at the same time. If the impacted mass occupy the rectum within reach of the finger, it can be broken up by an instrument, or even the handle of an ordinary spoon, and the action of the enema is greatly assisted by this means. Other ingredients may be employed for the purpose of softening and disintegrating the masses, such as brewer's yeast, six to eight ounces used pure, or ten to fifteen ounces of pure olive oil, or eight ounces of ox-gall mixed with an equal quantity of water, as recommended by Dr. W. Murray; but to be efficacious these injections must be introduced very slowly and gently, so that they may be retained as long as possible.

Eustace Smith.

CONSTIPATION, HABITUAL.—The prevention of **Atonic Constipation** must be sought by inculcating regular habits in the matter of emptying the bowel, insisting on the necessity of taking food which contains a due proportion of cellulose, and on the importance of daily walking or riding exercise, which is perhaps the best natural stimulant of intestinal peristalsis. The importance of green vegetables and fruit as articles of diet is constantly overlooked, so that they form no regular part of the dietaries of children at school or of the inmates of many institutions, while they are regarded as superfluous by a large part of the people who, from motives of economy and time as well as from not understanding their importance, do not give themselves the trouble to provide them. The importance of daily exercise is more generally admitted, and happily with a large part of our population a sufficient amount of walking is still inevitable.

The *Special Diet* that should be used by persons with a tendency to constipation should include either porridge or brown bread, and uncooked fruit or uncooked vegetables, such as salads and cresses, with each meal; where these articles of food cause indigestion, it may be impossible to persist in their use, but we may content ourselves by substituting well-cooked green vegetables and stewed fruit, such as pears, apples, figs, and plums.

It is also probable that many constipated persons drink too little water, and that it may be actually necessary to prescribe a certain amount to be drunk in the course of the day, although it should not be hard water. Constipated persons should avoid red wines, should not drink milk with their meals, and China tea may well replace the more astringent varieties from India and Ceylon.

Of the places at which mineral-water cures for the treatment of constipation may be obtained, Marienbad unquestionably stands first. Its waters belong to the group of sulphated alkaline waters, and contain sulphates, chlorides, and bicarbonate of sodium, with free carbonic acid gas. Of the group of mineral water stations near Frankfort, Homburg is the most popular. There are several springs at Homburg, of which those used for intestinal troubles contain chiefly sodium chloride, with chlorides and carbonates of the alkalies and alkaline earths. These waters do not contain salts which are generally regarded as purgative, but in the quantities given, their action is effective. Kissingen is no longer fashionable with English people, but its waters are suitable for the treatment of constipation; they contain chiefly chlorides of the alkalies with carbonic acid gas.

The waters of Harrogate are beneficial in chronic constipation, but the type of person which derives most benefit from them is the obese, full-blooded, gouty patient of middle or past middle age, and harm may be done to delicate people. The waters contain chiefly common salt, with a little sulphate of soda and a large amount of sulphuretted hydrogen. Cheltenham waters are highly suitable

for the treatment of constipation, as many of the springs contain sulphate of magnesia, sulphate of soda, and common salt; in some respects they compare favourably with the foreign waters which have been mentioned; but the wave of fashion has receded temporarily from the Gloucestershire spa.

Although nothing is really equal to the natural exercise of walking and riding, yet, where from age or obesity these become difficult, or there is want of will to persist, they may be in part replaced by regular exercises which can be followed out in the dressing room or by passive movements. Abdominal massage, alone or combined with electricity, either by making the hand an electrode or by giving a short faradic sitting after or before the massage, or the mechanical kneading of the abdomen performed by a machine in a Zander Institute, such as exists at Bath and at most foreign spas, helps to stimulate peristalsis. Electricity may also be applied by a large flat electrode over the abdomen, through which a slowly interrupted galvanic current of from 5 to 10 milliamperes may be passed for ten or fifteen minutes.

Some patients find benefit from the application of a wet abdominal compress worn for some hours.

The Drugs prescribed for constipation are so numerous that it is impossible to name them all; it will be sufficient to draw attention to those which are most used. It is desirable that an aperient should be one which can be taken for a long period of time without doing harm, and therefore we would not include under this head the preparations of mercury which, although very useful for clearing out the bowel when that may be desirable, are obviously not suitable for daily use. It is also desirable that the aperient used should be one which can be easily regulated, mild in its action, and equal in its effects, so that a given dose may be relied upon to produce only a known effect. On the whole, mineral waters, or the salts which constitute the purgative base of these waters, best fulfil these requirements; but many delicate invalids, especially neurasthenics, find saline aperients depress them. Of these aperients the sulphate of soda is the most pleasant, and is as trustworthy as its less palatable rival, sulphate of magnesia. The plain sulphate of soda may be given dissolved in a small quantity of hot or cold water, with directions to sip it slowly either before getting out of bed, or directly after rising in the morning. A pleasant modification is to use the effervescing form of the powder, but it should be sipped slowly in the same way as the plain salt. The principal mineral waters containing sulphate of soda are Carlsbad, Rubinat, and Condal. The quantity of sulphate of soda to be taken must be regulated by the requirements of each case; about a teaspoonful is usually the best dose to begin with, or a wine-glassful of the mineral water.

Phosphate of soda is a mildly aperient salt, which is also sold in an effervescing form; the dose and mode of administration are the same. Sulphate of magnesia, from its bitter taste, is not so popular, but is a very effective aperient, and can be obtained as an effervescing powder. Seidlitz powders are still liked by many patients, although their action is rather uncertain and apt to cause sharp purging. This is probably due to the addition of sulphate of magnesia to heighten their effect. The proper Seidlitz powder should contain only sodium potassium tartrate (Rochelle salt) and sodium bicarbonate with tartaric acid.

Liquid paraffin has of late become a popular aperient; it has the advantage that it is not absorbed, and acts mechanically by softening the fæces and stimulating peristalsis. The dose is from a teaspoonful to a tablespoonful once daily, or more frequently if necessary, before meals.

The vegetable aperients most in favour are the various preparations of senna, cascara, and aloes. Senna is the mildest and, perhaps for that reason, the

most popular of these drugs, but has acquired, not altogether with justice, a reputation with the profession for causing griping, which seems only to occur when it is used in large doses ; it forms the principal ingredient in the compound liquorice powder (*pulvis glycyrrhizæ compositus*) and the official confection and syrup. The official preparations are all made from the leaves, but the legumes or pods also contain a purgative principle, and are somewhat extensively used at the present time. Many patients find that a cold infusion of from eight to ten of the pods in 3 or 4 oz. of water taken every night at bedtime is a very efficient remedy ; or a few of the pods may be stewed with prunes, and then picked out, the prunes and accompanying syrup forming an agreeable mild aperient. The well-known syrup of figs is said to owe its efficacy to a watery extract of senna pods.

The various preparations of *cascara sagrada* act more powerfully. The fluid extract has a strong bitter taste, which is covered with difficulty by syrup and aromatic drugs. It is, therefore, preferable to prescribe it in capsules or pills. A preparation sold under the name of *Cascara evacuant* is free from this objection, as the bitter principle has been removed. The dose of the dry extract is from 2 to 8 gr., and it may be given every night at bed-time, or in obstinate cases, three times a day before meals.

Aloes in its various preparations, especially aloin, is a favourite remedy with many practitioners, and forms, as is well known, the active principle of a large number of pills, in combination with *nux vomica* or strychnine and belladonna. The dose and modes of administration are so well known that they need not detain us.

Phenolphthalein is a comparatively recent addition to our stock of aperients, and has had the advantage of a good deal of advertisement ; it is regarded by some practitioners as an excellent remedy, but is still on trial ; the dose is from $\frac{1}{2}$ to 10 gr.

Sulphur is a good laxative, its action being mild and certain, but it has the disadvantage of causing offensive stools. It is contained in the compound liquorice powder to which reference has been made. It is often given in the form of the official confection (*confectio sulphuris B.P.*) either alone or with an equal quantity of the confection of senna. The tablets of guaiacum and sulphur, recommended some years ago by Sir Alfred Garrod, are frequently employed on account of their slight laxative action. A similar combination exists in the well-known Jephson's powder, which is composed of two parts of precipitated sulphur and one part of powdered guaiacum, of which the usual dose is a teaspoonful ; it is a rather powerful laxative, although harmless, and may be taken suspended in milk.

Castor oil is well known for its mild and certain effect, but its nauseous taste is an objection to its frequent use, although nothing is better when it is desirable to get the bowels to act after they have been confined for some days ; in these circumstances a dose of $\frac{1}{2}$ oz. to 1 oz. is required. Small doses may be given in capsules ; in the constipation of old people it acts very well, in doses of $\frac{1}{2}$ dr. to 1 dr. A better way of giving it is with an equal quantity of glycerin, taken either at bedtime or the first thing in the morning ; this mixture is not unpleasant to take, but can be ordered in capsules if preferred. A powdered form of castor oil, *pulvis olei ricini*, has been introduced quite recently ; it is nearly tasteless.

Enemata have never become such popular remedies for habitual constipation in this country as on the Continent, a belief being generally entertained that they ultimately weaken the action of the bowel. Their utility is fully recognized by the profession as a means of emptying the lower bowel in all cases where we are in doubt as to the diagnosis, or suspect the presence of local ulceration, and desire to unload the bowel in the gentlest manner, or where an accumulation

of inspissated fæces exists which cannot be expelled. Enemata should be employed where laxatives fail, as in the atonic constipation of women, in the constipation of typhoid fever, or whenever the patient is very weak, as their action is mild and confined to the lower bowel. Larger enemata can be given, and not uncommonly copious irrigations are used in the hope of filling the whole of the colon with fluid, and so modifying its contents. Enemata often cause considerable pain, and should, therefore, be given slowly, the quantity being regulated by the feelings of the patient. The use of a long tube passed up the bowel beyond the region that can be explored with the finger is not recommended; if employed, the tube should be of soft rubber like a stomach-tube, but of somewhat greater diameter, and it should be introduced without the use of any force, and never where there is reason to think there may be ulceration of the bowel; it is a method which always has in it some element of danger, and is rarely, if ever, necessary. An enema should consist of from $\frac{1}{2}$ to $1\frac{1}{2}$ pints of fluid; this may be plain soap suds or thin gruel, and to either of these bases may be added 1 oz. of castor oil or glycerin, or 1 oz. of castor oil with $\frac{1}{2}$ oz. of turpentine. The temperature of the enema should be about that of the body. Large enemata of olive oil are sometimes used for softening masses of fæces. Rectal injections of glycerin by means of a vulcanite syringe, the quantity used being about $\frac{1}{2}$ oz., are a popular and effective means of producing an action of the bowels.

All means that involve the introduction of a syringe are obviously inapplicable in cases where there is a tendency to piles, and very frequently after they have been employed for a few days the local disturbance causes so much soreness that, in spite of gentleness and care, other methods of acting on the bowel have to be employed; but this rarely occurs where the enema is only used once every two or three days, and is not continued for more than a few weeks.

In the treatment of **Spasmodic Constipation** it is necessary to avoid those articles of food previously recommended, on account of their containing a certain proportion of indigestible cellulose in the shape of fibre, seeds, and membrane, which stimulate the muscular coats of the bowel. We must forbid the use of porridge and brown bread, uncooked fruit, and raw vegetables such as salads and cresses, and order even cooked fruit which contains seeds and skins to be passed through a hair sieve. As these cases are invariably associated with neurasthenia, the hygiene and mode of life should be so regulated as to improve the general health. This is undoubtedly best effected by change of scene, with residence in a bracing place; but if the case be too far advanced to benefit by these means, a complete rest cure of at least three months' duration should be carried out. During this period, general massage of the trunk and limbs is desirable; abdominal massage does more harm than good, and if permitted at all must be of the very gentlest kind. Gentle rubbing of the abdomen with the hand sometimes seems to relieve pain, but it must be cautiously carried out. Electricity, if employed at all, must only be used in the shape of a weak galvanic current applied by means of a flat electrode large enough to cover the whole of the abdomen. Abdominal compresses and fomentations give relief, and their use may be combined with the rest cure. Liquid paraffin should be tried, $\frac{1}{2}$ oz. at bedtime.

Castor oil or glycerin enemata may be given. Olive oil enemata at the temperature of the body are very soothing to the bowel, as well as effectual in overcoming this form of constipation. Four to eight ounces of olive oil should be introduced slowly into the rectum and if possible retained in the bowel all night, a folded towel being placed between the nates to prevent the bed-clothes being soiled.

Robert Saundby.

CONVULSIONS, INFANTILE.—Convulsions in infancy and childhood may be considered under the following headings: (1) Eclampsia neonatorum; (2) Pre-dentition convulsions; (3) Convulsions during the period of primary dentition; (4) Convulsions occurring between primary and secondary dentition.

1. Eclampsia Neonatorum.—Convulsions in the newly-born may be asphyxial, due to supervenosity of blood and venous turgidity arising from prolonged and difficult labour, especially in the first-born. Cyanosis is frequently present in such cases, and the treatment then consists in the application of leeches—one to each mastoid process—or in actual blood-letting.

Willis, in the 17th century, having seen a series of infants in a single family, die of convulsions shortly after birth, bled the next arrival at once, and claimed that it escaped convulsions and survived, in consequence of his treatment.

Blood-letting is only justifiable when the infant is obviously healthy, though plethoric. Pallid, puny, and anæmic infants who become convulsed shortly after birth should be treated by warmth, stimulants, and saline injection sub cutem.

Convulsions from Cortical (meningeal) Hæmorrhage at Birth.—Prolonged and difficult labour suggests this cause. Supracortical hæmorrhage, if not fatal, causes various kinds of birth-palsy—spastic hemiplegia, paraplegia, or diplegia, with or without epilepsy, and mental deficiency. Hence, if diagnosed, operative measures are clearly indicated. Unfortunately, focal commencement of fits is not an infallible guide to diagnosis, even when transient local paresis or paralysis of a limb or limbs follows the convulsions. Such paresis must be persistent, or there must be rigidity of the affected limbs, and the convulsions must be invariably of Jacksonian type, in order to justify the diagnosis of cortical hæmorrhage and recommendation of craniectomy.

2. Pre-dentition Convulsions, in the absence of traumatism, organic disease of heart, lungs, and kidneys, congenital syphilis, otitis media, and the various forms of meningitis, simple, basic, purulent, and tuberculous, are usually traceable to improper food or over-feeding. A highly neurotic family history suggests predisposition to fits, which may be induced by very trivial disorders of digestion.

Inward convulsions are so called for the excellent reason that the infant is not outwardly convulsed, but merely rolls its eyes, moans or grins, clenches its fists, and draws up its legs at frequent intervals.

In some cases, the infant suddenly ducks its head, and doubles up its body or straightens it out, the breath is held for a few seconds, and a scream or moaning cry of pain follows. Consciousness is not lost. Most of the above-mentioned seizures are due to colic.

A dose of castor oil, with half to one and a half minims of laudanum, usually puts a stop to them, and prevents recurrence, if suitable diet be supplied.

3. Convulsions during the Period of Primary Dentition.—In healthy children whose gums are also healthy, dentition is a painless process. It is painful only when the gums are tender, swollen, and inflamed. It is then associated with pyrexia, catarrh—naso-pharyngeal, mid-aural, bronchial, or pulmonary—and far more frequently with gastro-intestinal disturbance—vomiting, colic, diarrhœa, or constipation. All these conditions may render the gums tender and unhealthy, and so the passage of a tooth gives rise to pain and irritation, and, in neurotic infants, may cause convulsions.

Yet an infant who at one time cuts a tooth with some or all of these symptoms, may cut the next without any discomfort. Hence coincident ailments, rather than dentition itself, are the probable cause of “teething convulsions.” A fretful, feverish infant is almost invariably over-fed; thus its sufferings are aggravated and convulsions are induced by colic, not by teeth.

“Teething Convulsions.”—When, in the case of convulsions, the gum over an erupting tooth is obviously swollen, tender, and painful, it should be lanced. But gum-lancing without such indications should not be practised. Catarrh and colic are more potent causes of convulsions than dentition. The practice of gum-lancing seems to have been abused when the gums have been generally swollen, dry, tender, and inflamed, as though all the teeth were trying to come to the surface at once. This condition is the result of feverish catarrh, most frequently gastro-intestinal in site. A brisk purge—castor oil is the best—should be given, with half to one and a half minims of laudanum; and a low diet of pure milk, well diluted with barley-water, should be prescribed. Protection from chill is important. Restless, feverish infants who are supposed to be “merely teething,” should not be taken out of their cots to look at the moon on frosty nights.

Earache from middle-ear catarrh is a common cause of symptoms (including convulsions) supposed to be those of dentition. Any infant, except a congenital idiot, will indicate the site of its pain by pulling its ear and rolling its head when suffering from otalgia. If recognized early, blistering to the mastoid process, and hot dry applications to the external ear, will often relieve. A leech to the mastoid process of infants who are robust is effectual. Puncture of the membrana tympani, even when the membrane is not bulging but is merely congested, is sometimes strikingly successful in cases of apparent basic meningitis associated with fits (meningismus).

The generally swollen and tender condition of the gums mentioned above should be treated by scrupulous cleanliness, and by application of glycerin of borax (B.P.) with chlorate of potash, 10 gr. to 1 oz., with which the gums should be gently rubbed. Chlorate of potash also may be given internally in all cases of stomatitis or gingivitis present during dentition.

4. Convulsions between Primary and Secondary Dentitions.—Excluding gross meningeal and cerebral diseases as causes after the second year of life, colic from improper or excessive feeding is held to take the first place. Convulsions in such cases are usually regarded as produced by reflex irritation. But they may also depend on absorption of toxins produced by unwholesome and decomposing food. Toxæmic convulsions may also result from severe burns and scalds, and may occur as uræmic symptoms.

Reflex convulsions have been attributed to diseased or impacted teeth, to errors of refraction, especially astigmatism, to diseases of the throat, nose, and ear, to the presence of foreign bodies in the various orifices of the body, to phimosis and balanitis, and to the presence of intestinal parasites.

It is the duty of every practitioner in a case of convulsions to search for any condition which may have lowered general health, and to rectify it if possible. But convulsions are more often the indirect than the direct result of any of the so-called “reflex irritations” enumerated. In many cases a hopeful prognosis based on the removal of thread-worms or of a prepuce, or the correction of astigmatism, leads only to disappointment.

Fits, as the result of an exanthem, are certainly rare, and when they occur it will usually be found that the child has had them before, or becomes liable to them afterwards.

Of psychical causes, fright or shock must be mentioned, and in such cases recurrence may be expected, if not diminution of intelligence.

Infantile Convulsions in General.—Treatment aims at stopping the fits, removing the exciting cause, and preventing recurrence.

Hot baths, with or without mustard, and mustard packs, are of doubtful efficacy, but may relieve colic when present.

Ice to the head should be used when there is hyperpyrexia, and the patient

should be placed in warm water, which should be cooled gradually to 50° or even 40° F. In all cases, the lower bowel should be washed out with saline solution (1 dr. to the half pint of warm water). Then a rectal injection of chloral and bromide, 3 to 5 gr. of the former and double or even treble the quantity of the latter,* in 2 oz. of water, for a child of six months of age, should be given.

Inhalations of chloroform may be used to allay spasms until the injection has become absorbed.

Inhalation of nitrite of amyl is recommended by some, and hydrobromide of hyoscyne in hypodermic injection of $\frac{1}{200}$ to $\frac{1}{100}$ gr.† is said to be useful in protracted cases of convulsions. It is, however, not free from danger in debilitated infants. Injections of morphia ($\frac{1}{50}$ gr.)* for a child of six months are preferable to those of hyoscyne, but should never be repeated within twelve hours. When cyanosis is present, leeching or even venesection should be employed; provided that the infant is fairly strong, $\frac{1}{2}$ to 1 oz. of blood may be abstracted.

Emetics are never advisable, but the stomach should be washed out if there is any suspicion of its containing poison or irritants of any description. Of all emetics mustard is the most dangerous.

Whilst treatment is in progress, the probable exciting cause of the convulsions should be ascertained by observation and enquiry. Whatever this may be, a full dose of calomel or castor oil never does any harm, and often has the best effects when given after the convulsions have ceased. After-treatment consists in keeping the child quiet, and warm or cool, as indicated by the temperature. Attention to diet is of course all important, for the vast majority of infantile convulsions are set up by gastro-intestinal disturbance.

Reflex sources of irritation, such as nasopharyngeal obstruction, worms, local genital complaints, ear and eye troubles, should be attended to. Rickets should be treated in the usual manner.

Leonard G. Guthrie.

CORNEA, DISEASES OF.

ULCERATION OF THE CORNEA.

A thorough examination of the whole cornea must be made at the first visit. If there is *blepharospasm*, it must be overcome by the instillation of cocaine drops, by the careful use of lid-retractors, or if necessary by giving an anæsthetic. The greatest care must be exercised lest a deep ulcer be perforated by rough manipulation. If there be any doubt as to the limits of the ulcer, it should be defined by staining with a solution of fluorescein‡.

The following are the chief points to be attended to: (a) Is the ulcer clear or infiltrated? (b) Are the edges sharp or rounded? (c) Is the ulcer superficial or deep? (d) Is there hypopyon? (e) Is the anterior chamber shallow or deep? (f) Has the ulcer perforated or not, and if so, is there any anterior synechia or prolapse of iris?

In treating an ulcer of the cornea, we must (1) Remove the cause; (2) Prevent spreading of the ulcer; (3) Keep the conjunctival sac clean; (4) Bandage and give rest and sedative treatment, hot applications, atropine; (5) Attend to the general health.

* Doses of this size are not devoid of danger.—AMERICAN EDITOR.

† The use of hyoscyne in infancy is considered particularly dangerous.—AMERICAN EDITOR.

‡ Fluorescein 8 gr., sodii bicarb. 12 gr. to the ounce. One drop is instilled into the eye, followed by a few drops of boracic lotion or solution of cocaine. The ulcer stains green.

§ An infiltrated ulcer is whitish-yellow in colour, either all over or at the spreading margin; its edge is sharp or undermined, the surrounding cornea is stippled and hazy, and the eye is injected.

A healing ulcer has, as a rule, a clear base; its edge is rounded, the surrounding cornea is clear, and the injection is passing off.

1. With ulcers of doubtful origin, the lid margins should be carefully searched for *inverted lashes*, which by rubbing the cornea may be the cause of the ulcer; these should be epilated. The upper lid also should be everted and examined for a *foreign body* which may be scratching the cornea.

2. If the ulcer is *infiltrated or spreading*, it must be cauterized, either with the platinum loop (electro-cautery) or with pure carbolic acid. For this a general anæsthetic is necessary only in children; the cornea can as a rule be rendered quite insensitive by four or five instillations of a 2 per cent solution of cocaine at intervals of two minutes. The ulcer is defined by a drop of fluorescein, all excess of stain being washed away. While cauterizing, the lids are separated and the eyeball steadied with the fingers of the left hand. This is a better plan and less painful than using a speculum and attempting to fix the eyeball with forceps.

If the platinum loop is used, the ulcer is thoroughly cauterized wherever it is infiltrated, and any overhanging edge is burnt away.

If pure carbolic acid is used, the ulcer should first be carefully cleansed with the spud, and any overhanging margin scraped or cut away with the small sharp-spoon or with scissors. It is then well dried with a corner of clean blotting-paper, and the carbolic acid stippled on with a very small camel's-hair brush, which is only just moistened with the acid. The blotting-paper should be applied frequently to prevent spreading of the acid beyond the edges of the ulcer. In this way the whole ulcerated surface is cauterized, and the effect should be as localized as if it were done with the actual cautery.

3. If there is much conjunctival discharge, the lids should be painted daily with a 2 per cent solution of silver nitrate, only so long as this lasts. The conjunctival sac should be washed out with warm boracic lotion three times a day, and the bandage over the eye dispensed with, the eye being protected with a loose flap of borie lint held in position by a bandage round the forehead only. Pressure should be made over the lachrymal sac to see if there is a mucocele (*vide infra*).

4. *Rest* is secured by the use of atropine, which paralyzes the ciliary muscle, dilates the pupil, and prevents the formation of posterior synechiæ. In young people, atropine drops or ointment (4 gr. to the ounce) should be used three times a day to keep the pupil well dilated. With elderly patients, and especially when the anterior chamber is shallow, atropine must be given with great caution, lest we induce an attack of glaucoma. In doubtful cases, homatropine drops, 2 gr. to the ounce, which can easily be overcome with eserine, may be tried tentatively, and, if no rise of tension occur, we may proceed to the use of atropine drops, 1 or 2 gr. to the ounce. If glaucoma complicates an ulcer, eserine must of course be used in place of atropine.

A light bandage should be worn, sufficient to keep the lid down and at rest. The only exception to this is when there is profuse conjunctival discharge, when a bandage is contra-indicated (see above).

Hot applications are most comforting to the patient. We can use either hot bathing, hot fomentations, the Japanese muff-warmer, or Maddox's electric pad where low-voltage electricity is obtainable. Hot bathing with a pad of cotton-wool dipped in very hot boracic acid lotion and placed over the closed lid should be carried out four or five times a day for a quarter of an hour at a time, frequent additions of boiling water being made to keep the lotion as hot as can be borne. Hot fomentations are very comforting, and may be applied between the bathings, but unfortunately they soon get cold. They should be made with several layers of boracic lint, a large piece of protective, and plenty of wool. When damp heat causes a sodden condition of the lids, dry heat may be substituted by means of the small muff-warmer or the electric pad.

5. Attention to the general health is most important, especially in phlyctenular

keratitis and in chronic ulceration of the cornea, the bowels being regulated, and light nourishing diet and tonics given, and plenty of fresh air.

Simple Ulcer.—Hot bathing, atropine, light bandage, and tonics, are all that is necessary. The patient is not confined to bed unless the ulcer is spreading, or deep and liable to perforate.

Infiltrated Ulcer.—This must be cauterized (*vide supra*) and then treated as simple ulcer. If the ulcer shows signs of spreading after three days, it must be cauterized again.

If a spreading ulcer is complicated with a *mucocele*, and continues to spread in spite of the above treatment and careful daily syringing of the lacrymal sac with 20 per cent solution of protargol, the sac should be excised, or the eye may be lost.

Hypopyon Ulcer.—The patient should be kept in bed, the ulcer cauterized, atropine used six times a day until the pupil is well dilated, and heat constantly applied; a purgative should be given and the diet regulated.

If the hypopyon increases in spite of treatment, it must be let out by paracentesis of the cornea. A general anæsthetic should be given, as cocaine does not anæsthetize an inflamed eye properly; fixation of the eye is almost unbearable, and the pain after emptying the anterior chamber is very severe. After washing out the conjunctival sac, a broad needle is passed into the anterior chamber, parallel with the surface of the iris, at the lower edge of the cornea—1 mm. inwards from the sclero-corneal junction. The lower lip of the incision is then depressed with the curette, to allow the hypopyon to escape; if this is sticky and does not come out readily, it may be pulled out with smooth iris forceps, or washed out with sterilized normal saline solution. After the hypopyon has been let out, the repositor is used to make sure that there is no inclusion of iris between the lips of the incision. Atropine ointment is inserted between the lids, fomentations are applied, and the eye is bandaged.

Perforating Ulcer.—If perforation is liable to occur, the patient should be kept in bed, and all manipulations should be very gentle. In cauterizing an ulcer which is about to perforate, the margin should be dealt with first, and finally the base; and it is often a good plan to allow the cautery just to burn through the base and so let out the aqueous and any hypopyon that may be present.

When perforation has occurred and there is prolapse of the iris, the prolapse in most cases should be left alone. When, however, the prolapse is very minute and recent, and there is little or no conjunctival discharge, it may be picked up in the forceps, drawn well out, and cut off close to the cornea, and the iris allowed to retract. This should not be done if the opening in the cornea is larger than 1 mm. in diameter.

When the whole of the pupillary area is entangled in the corneal opening, secondary glaucoma will result as soon as the anterior chamber ceases to leak. An iridectomy should be performed in these cases directly the conjunctival sac is clean.

When the corneal scar will not flatten down, an iridectomy should also be performed, freeing the iris, if possible, from the back of the cornea. When owing to the peripheral situation of the adhesion the entangled portion of the iris cannot be freed, an iridectomy is done on one side, or if necessary on both sides, of the entanglement, and the eye kept carefully bandaged till the cornea is thoroughly consolidated.

Blind eyes with staphylomatous corneæ should be excised, or—after thorough evisceration—a glass globe may be sewn into the sclerotic (Mules' operation).

Keratocele.—Sometimes in the floor of an ulcer which has nearly perforated, a small, black-looking protrusion is seen, which is due to a bulging of Descemet's

membrane. The ulcer is treated in the ordinary way, and a firm bandage is applied. If the keratocele remain, thus preventing the proper healing of the ulcer, it should be pricked with a broad needle (taking care not to injure the lens capsule), the aqueous evacuated, and the bandage again applied.

Dendritic Ulcer should be cauterized with pure carbolic acid (*vide supra*), and if in three days the ulcer is spreading, it should be cauterized again. In obstinate cases the actual cautery is more effective than carbolic acid.

In **Neuropathic Ulcer**, in which there is loss of corneal sensation, we must be very careful to avoid strong caustics. The eye should be washed out with hot quinine lotion (2 to 4 gr. to the ounce) four times a day, hot fomentations applied, atropine instilled, and the eye carefully tied up: either the hydrochloride or the sulphate of quinine is used, but if the latter, it must be dissolved with the smallest possible addition of weak sulphuric acid. If the ulcer does not get better quickly, the lid margins should be pared and sutured together along their outer halves, to give a greater protection to the cornea.

PHLYCTENULAR CONJUNCTIVITIS AND KERATITIS.

Phlyctenular disease being an indication of lowered nutrition, the main object of treatment must be to improve the general health, in order to cure the disease and prevent recurrence. The child should be given plenty of fresh air and light nourishing food, and, except in the worst cases, he should be allowed to run about out of doors, both eyes being protected by a broad shade or dark glasses. In the initial stages mercury is indicated to cleanse the intestinal tract (hydrarg. c. creta with sod. bicarb., three times a day), followed after a few days by syrup of the phosphate of iron, or malt and cod-liver oil.

LOCAL TREATMENT.—

Phlyctens of the Conjunctiva.—Hot boracic bathing, followed by application of yellow oxide of mercury ointment, 4 gr. to the ounce, twice a day, and the use of a broad shade over both eyes. The ointment is inserted between the lids with a small round-ended glass rod. When associated, as is commonly the case, with catarrhal conjunctivitis, the conjunctival sac should be painted every other day with 2 per cent silver nitrate till the discharge ceases.

Phlyctens at the Margin of the Cornea.—In addition to the above treatment, atropine, 2 gr. to the ounce, should be added to the yellow oxide ointment till healing is well advanced; it can then be discontinued. Here also any catarrhal conjunctivitis must be treated as mentioned above.

In those cases in which a marginal phlycten begins to travel across the cornea, dragging a leash of vessels after it (fascicular ulcer), the same treatment is adopted, but the grey advancing crescent must be cauterized, preferably with the actual cautery. These ulcers do not perforate, but if they cross the pupillary area the resulting scar severely impairs vision, so that their career must be checked at the earliest possible date.

Phlyctens of the Cornea proper are dangerous, both from their liability to perforate and from the scars which they leave; indeed, after repeated attacks the whole cornea may become covered with a vascular coat (phlyctenular pannus), which in addition to the nebulae left by the ulcers, seriously impairs the sight. In this group it is very important to give soothing treatment till healing has begun. We therefore withhold the oxide of mercury, and give atropine ointment alone, 4 gr. to the ounce, till healing is well advanced. Great attention must be given to the general health, in addition to local treatment, hot bathing, protection from light, etc. If the ulcer is infiltrated it must be cauterized (see above, **INFILTRATED ULCER**).

There is often marked *blepharospasm* in phlyctenular disease, and this is best treated by dipping the face into a basin of cold water and holding it there till

the child struggles for breath, once or twice a day, as is necessary. The conjunctiva should be treated with nitrate of silver if there is catarrh, and *cracks* at the outer canthus touched with a sharply pointed stick of nitrate of silver.

INTERSTITIAL KERATITIS.

In the interstitial keratitis due to inherited syphilis, we have to treat not only the cornea, but the irido-cyclitis which almost always accompanies the keratitis, and indeed in some cases occurs as an initial phase.

Locally we give dark glasses, hot bathing, and atropine four times a day to keep the pupil dilated and to prevent the formation of posterior synechiæ. The tension should be watched, lest the irido-cyclitis cause secondary glaucoma (see GLAUCOMA). The general state of the patient must be looked after, and tonics should be given. Mercury and iodide are of service provided they do not impair the health, but they are, curiously, not of so much use here as in other syphilitic complaints. Neo-salvarsan is worth trying, but is often disappointing in its results. Two or three injections should be given, but even after these, in many cases the course of the disease appears not to be affected. Sometimes, however, neo-salvarsan seems to cut short the attack and favour the clearing up of the cornea.

In the late stages, when inflammation has subsided, massage of the cornea with yellow oxide of mercury ointment (4 to 8 gr. to the ounce) helps to clear the cornea.

HERPES OPHTHALMICUS.

The common ocular affection in this condition is an interstitial infiltration of the cornea, associated with more or less cyclitis. The cornea is also rendered insensitive to a greater or less extent. Our treatment must therefore be: (1) Protection of the cornea from irritants by a bandage or dark glasses: (2) Sedative applications, such as hot bathing and atropine. (*N.B.*—Unfortunately the cyclitis often raises the tension slightly, and atropine may make this worse; hence it must be exhibited with caution, very weak drops (1 gr. to the ounce) being used at first to see if the tension be increased or not. If it is increased, atropine must be withheld, and we must rely on hot bathing and leeching. If ulceration occurs, similar treatment is adopted.)

General treatment should be directed against any gouty tendency that may be present. In some cases, potassium iodide and arsenic are of service; in others Tweedy's pill does great good:—

R. Quinina Sulphatis	gr j	Extracti Belladonnæ	gr ʒ ^{ss}
Calomel	gr ʒ ^{ss} - 1	Confectionis Rosæ	q.s.

To be taken three times a day after food.

The severe neuralgia occasionally met with can only be relieved by morphia; but the use of this must be withheld as long as possible, as the duration of the neuralgia is often prolonged.

CONICAL CORNEA.

The vision is often greatly improved by glasses, especially a high concave or convex cylinder, which may at times give surprising assistance. When glasses are of no use, and both eyes are affected, an operation holds out a good chance of improvement in many cases, either cauterizing the cornea or removing an elliptical portion from the apex of the cone.

W. Tindall Lister.

COUGH.—(See BRONCHITIS, CHRONIC.)

CRAFT PALSIES.—In every one of these, whether writer's cramp, or the cramp of pianists, violinists, telegraphists, typists, tailor's cutters, hair-cutters, hammer-men, cow-milkers, watchmakers, harpists, cigarette-makers, etc., etc., we should bear in mind that the craft palsy is essentially a cerebral fatigue; that it comes on, not during the period when the sufferer is learning his occupation, but when he has become expert and has to perform the particular skilled movement for prolonged periods at a time. Moreover, the limb is perfectly normal for all movements except that particular one. Thus in writer's cramp the patient is able to use the hand normally in piano-playing or in grasping and using a heavy tool.

TREATMENT.—This is always tedious. Drugs are valueless, except perhaps an occasional tonic mixture in patients whose general health is below par. Massage, and electrical treatment of the affected muscles, are but palliative at best. In every case, what is essential is complete cessation from the particular movement which has produced the cramp.

In writer's cramp—the commonest and most typical of craft palsies—it is not enough for the patient merely to reduce the amount of his writing; he must give it up entirely for three months at least. Change of scene and avoidance of worry are easy to prescribe, but often difficult of attainment, inasmuch as the patient's livelihood often depends on that particular movement which brings on the cramp.

During the period in which he is not allowed to use the hand for writing, he may learn to use the other hand for this purpose, or, better, he may learn to use a typewriting machine. But even then, such patients may subsequently develop typist's cramp.

After the three months' rest from writing, the patient may begin to write again, but must employ a different method. A thick cork penholder is often of service, and he should be made to grasp it about its middle, not close to the point. Sometimes it is advisable to place the penholder between the index and middle fingers instead of between the thumb and index. In writing, the elbow must rest on the desk or table, the table must be placed at a comfortable angle, and the patient must write from the shoulder, not from the wrist or fingers. This is sometimes ensured by having a penholder which passes through a spherical piece of cork about the size of a hen's egg, so that the hand grasps the ball and moves *en masse*, fine digital movements no longer being called for.

Other professional neuroses are to be treated on the same lines as writer's cramp, complete rest being the first essential. Purves Stewart.

CRAMP.—In the cramp of **Over-fatigue**, the pain is best relieved by rest, by a hot bath, and by energetic massage, together with passive stretching of the affected muscles. Various liniments, such as liniment of belladonna (B.P.), of turpentine, of chloroform, or combinations of these, may be employed with benefit, to aid the rubbing and to produce an after-sensation of cutaneous warmth.

In the recurring nocturnal cramp associated with flatulent indigestion, an alkaline carminative draught at bedtime is often effective, e.g. :—

℞ Tincturæ Cardamomi Co.	℥xiv	Spiritus Ammoniaë Co.	℥vj
Spiritus Chloroformi	℥iv		
℥ij with an equal quantity of water for a dose.			

In the cramp of "**Intermittent Claudication**" (dysbasia angiosclerotica) rest is essential (the patient perforce rests while the pain lasts); whilst local hot applications, e.g., a hot foot-bath, together with massage, will benefit the pain. In addition to these, iodides and nitrates should be administered internally, in the hope of relaxing the arterial spasm which appears to be one of the underlying causal factors. Erythroltetranitrate is particularly valuable in such cases.

Many patients suffering from intermittent limp are inveterate and excessive tobacco smokers, and this, too, must be corrected.

The treatment of the cramps due to strychnine poisoning, tetany, tetanus, and paralysis agitans is dealt with in other articles. *Purves Stewart.*

CRETINISM.—The treatment of cretinism in a child is more difficult than that of myxœdema in the adult, as it has to be carried on during the active period of bodily growth and mental development. Ultimate success depends upon the diagnosis being made, and the treatment commenced, at the earliest possible date. If this is done, and the treatment is adequately and continuously kept up, the child's mental and bodily development should make steady and normal progress equal to that of other children of the same age. If, on the other hand, the disease has been allowed to develop for months or even years without treatment, the arrest of mental development is so great that it is unlikely that the mental powers will ever reach the same level which might have been attained if treatment had been carried out from the commencement of the disease. The same does not apply so strictly to the physical development of the child, for it is remarkable what rapid physical progress may be made in a case of cretinism, even of some years' duration, the lost time being largely made up by the unusually rapid rate of growth which takes place under treatment, while mental development lags behind.

The treatment of an early case of cretinism is carried out in much the same manner as that of myxœdema in the adult. At the commencement, a small dose of 1 to 2 min. of liquor thyroidei (B.P.C.), or $\frac{1}{2}$ to 1 gr. of dry thyroid in a powder or tablet, should be given each night. The dose may be increased gradually by the addition of 1 min. every week, according to the progress made, until from 5 to 10 or even 15 min. (one to three $2\frac{1}{2}$ -gr. tablets) is reached, according to the size of the child. If excessive doses are given, the pulse becomes too frequent, the weight diminishes, pains may be felt in the limbs, the temperature may rise, or diarrhœa may be set up. In some cases the long bones of the legs are liable to become bent during the earlier stages of the treatment. If this should occur, the child should not be allowed to stand or walk for several weeks.

When the cretinism is even of ten or fifteen years' duration, striking results can still be obtained. Larger doses, 3 to 5 min., of the extract may be given from the commencement, the effects being carefully watched. If any tendency to fainting appears, the patient should be kept in bed and very small doses given at first, which may be gradually increased.

The improvement in a cretin under treatment is remarkable, and often rapid. The swelling steadily diminishes and finally disappears, growth is resumed, and may take place very quickly, for as much as six inches has been gained in height in the course of six months. The temperature becomes normal, the skin moist, and the hair grows naturally. In the case of adult female cretins, menstruation becomes established and the mammary glands rapidly develop. After a time, mental development begins to progress, new words are learned, and the range of speech gradually increases. Special methods of education should be adopted, such as are suited to the actual stage of mental development which has been reached, rather than to the actual age of the patient. *George R. Murray.*

CROUP.—For the purpose of this article "croup" signifies catarrhal laryngitis or "catarrhal laryngeal spasm." Laryngeal diphtheria, which is sometimes spoken of as *true* croup, is dealt with separately. (See also LARYNGITIS.)

1. Treatment during an Attack.—The child should be placed in a warm bath, to which mustard is added (1 oz. to the gall.). An emetic should be administered, e.g., 10 gr. of powdered ipecacuanha or 1 gr. of subsulphate of mercury.

Ipecacuanha wine is not trustworthy. The child should then be placed in bed surrounded by an improvised "tent," into which steam is introduced from a bronchitis kettle. A hot fomentation should be placed over the larynx, plenty of hot liquids given to drink, and 2 gr. of calomel administered. If the stridor does not yield to these measures, and if dyspnoea becomes urgent and retraction of the lower interspaces marked, it may be necessary to proceed to intubation (see DIPHTHERIA and LARYNGEAL OBSTRUCTION). Should there be the least suspicion that the case may be one of true diphtheria, and not a mere laryngitis, an injection of antitoxin should be given (see DIPHTHERIA), and the child carefully isolated.

After the acute stridor has disappeared, the child must be kept in bed so long as there is any hoarseness, steam inhalations being employed for a quarter of an hour at a time several times a day, and fomentation of the larynx maintained. Five minims of antimonial and three of ipecacuanha wine should be administered every three hours.

For two or three nights following an attack, a dose of antipyrin (1 gr. for every year of the child's age), or of chloral in similar proportion, should be given at bedtime to prevent recurrence of spasm.

2. Preventive Treatment.—In order to prevent recurrence of attacks, the nose and pharynx should be thoroughly examined for obstruction from adenoids, etc., and these dealt with, if found. Exposure to damp air and sleeping in unwarmed rooms should be avoided. The throat and neck should be sponged daily with cold water, and the child gradually accustomed to open air and free ventilation. In weakly or anæmic children, a course of cod-liver oil and iron may be advantageous.

Robert Hutchison.

CURETTAGE.—(See ENDOMETRITIS.)

CUT THROAT.—In cases of suicidal or homicidal cut throat, the condition of the patient usually demands the immediate administration of a hypodermic of morphia. This should be done as the first treatment unless there is serious bleeding or respiratory embarrassment. Severe bleeding must be at once checked. If asphyxia threatens, in cases in which the air-passages are wounded, the wound in the trachea or larynx should be kept open; or if this fails to relieve or is impracticable, a temporary opening should be made through the cricothyroid space or into the trachea.

When no urgent symptoms are present, the surroundings of the wound should be carefully rendered as aseptic as possible, and the wound itself cleaned and examined to see if the administration of an anæsthetic will be required. When the wound does not extend deeply, this is not necessary; the wound should be sutured and provision made for drainage for the first twenty-four hours. If examination reveals that the wound is deep, or that important structures are divided, an anæsthetic should be given—chloroform or ether by the open method—and the wound thoroughly explored.

In wounds above the hyoid bone the condition of the muscles of the tongue should be investigated, and, if cut into, the cut edges brought together with chromic gut sutures. The bleeding points must be carefully tied, remembering the position of the lingual and facial arteries and their branches. When the region of the thyrohyoid space is the seat of the wound (the usual spot in suicidal cut throat), the danger of wound of the epiglottis must be remembered; it may be necessary to suture this structure or to remove a loose portion of it. All oozing must be carefully checked, the wound closed in layers, and drainage provided. If the larynx is involved, divided structures must be carefully united and the wound closed. If, from the nature of the wound or the

impossibility of stopping oozing, laryngeal obstruction is feared, a high tracheotomy should be done. Wounds of the trachea, if cleanly cut, may be completely closed, but if the edges are lacerated or contused it is advisable to insert a tracheotomy tube between the stitches for at least the first forty-eight hours. If the œsophagus is wounded, it should be sutured in layers and a tube put down to the suture line. The wound should be well dressed with cyanide gauze, and the patient's head flexed.

Great care is necessary in the *after-treatment*, particularly of cases of suicidal cut throat. The mental condition of the patient must be remembered. A nurse, male or female, must be in constant attendance, a male being preferable for a male patient. Shock may be out of all proportion to the severity of the wound, and may necessitate saline infusions, intravenously or by the rectum. The patient must be encouraged to take food, and in cases in which the base of the tongue, epiglottis, or œsophagus has been injured, food must be given through an œsophageal tube; if the patient refuse food by the mouth the same method of feeding must be adopted. Sleep must be obtained by suitable hypnotics, and every effort made to improve the general condition.

A careful watch must be kept for signs of respiratory obstruction, and tracheotomy performed if necessary. Early and free incisions must be made in the event of the development of cellulitis of the neck, and drainage provided.

After wounds in the thyrohyoid space an aerial fistula may develop; this will need a simple operation for closure. Laryngeal and tracheal stenosis may necessitate tubage or tracheotomy.

Aphonia, the result of division of the recurrent laryngeal nerve, may be present. An attempt to remedy this should always be made. As soon as it is seen that no infection of the wound will take place, the ends of the nerve should be sought and suture performed; if it is impossible to find the central end, the peripheral end should be anastomosed to the vagus or spinal accessory, or to a cervical nerve.

Esophageal and pharyngeal fistula may develop, but usually closes spontaneously.

James Sherren.

CYCLITIS.—(See IRITIS.)

CYSTITIS.—Inflammation of the bladder may be either acute, subacute, or chronic, and in all cases is due to infection with micro-organisms, either of a specific type, such as the typhoid bacillus, or the common organisms of suppuration.

Acute Cystitis.—**TREATMENT.**—Rest in bed is the first indication, with warm stupes or fomentations frequently repeated to the suprapubic region, and the hot sitz-bath two or three times a day. The baths should be taken really as hot as the patient can stand them, from 105° to 110° F. They are best given by placing the patient in a hip-bath, with the body and legs well wrapped in blankets. Hot water should be repeatedly added to keep up the temperature, and the stay in the bath should be from ten to twenty minutes. Upon leaving the bath the patient should be rubbed dry rapidly with hot towels and should return to bed, when the fomentations should be repeated.

The diet must be very light and easily assimilated; spices, peppers, and condiments of all kinds are to be avoided; milk, chicken and veal teas, jellies, broths, custards, and eggs, with light farinaceous foods, are indicated. Alcohol in any shape or form should be absolutely forbidden.

Plenty of liquid should be taken, for although this increases the diuresis, and so in the early stages may increase the frequency of micturition, it is desirable to render the urine as fluid and bland as possible. Hence such mineral waters

as those of Vichy and Contrexéville are to be recommended, and the milk may be diluted with them in any quantity.

Treatment by Drugs.—The drugs to be ordered vary with the nature of the cystitis, which may be of the acid or the alkaline variety. Very commonly the urine in an acute cystitis is highly acid in the early stages, and tends to alkalinity and ammoniacal decomposition as the case progresses. In such cases there is usually a mixed infection present, the bacteria of ammoniacal decomposition, of which the most common is the *Bacillus ureæ liquefaciens*, only making their presence felt as the cystitis progresses. In some cases an acute cystitis may remain acid throughout. In such cases copious doses of alkalies, together with urinary sedatives, should be given at frequent intervals. A very useful prescription is the following :—

R Potassii Bicarbonatis		Tincturæ Hyoseyami	℥ xxx
Potassii Citratis	āā gr xx	Infusi Buchu	q.s. ad ʒj

To be given every three or four hours until some relief is obtained, and then reduced in frequency.

Decoctions of uva ursi and of triticum repens are sometimes very effectual in relieving the scalding pains on micturition.

If vesical tenesmus is really acute, narcotics must be used, and the best way in which to administer them is by a rectal suppository containing $\frac{1}{4}$ gr. or $\frac{1}{2}$ gr. of morphia, repeated twice or thrice in twenty-four hours. Their administration should cease immediately relief from the most pressing symptoms is obtained. In the acute cystitis of gonorrhœa, and indeed in the majority of cases where the urine is acid in reaction, the oil of sandalwood in full doses exerts a marked calmative effect. In cases where great nausea is excited by the drug it should be given in capsules, but where the patient is fairly tolerant it exerts its action in the quickest and best manner when given in the form of an emulsion. The writer has found the following formula of great value :—

R Olei Santali Flaviss Puriss. (fresh)	℥ xv	Salol	gr v
Pulveris Acaciæ (fresh)		Spiritus Menthæ Piperitæ	℥ ii j
Potassii Bicarbonatis	āā gr xxx	Aquæ	q.s. ad ʒj
		Fiat emulsio.	

To be taken every four hours until evidence of its excretion by the urine is strongly marked by its characteristic scent, when the administration should be reduced in frequency.

It is essential that a regular and free action of the bowels should be obtained by the administration of such simple laxatives as compound liquorice powder, confection of senna, or such waters as Hunyadi Janos or Apenta. In addition, a daily enema of plenty of hot water, given very gently and carefully, and really hot, not only assists in emptying the lower bowel, but also is soothing and comforting to the patient.

In those cases where the urine is alkaline almost from the commencement, with an ammoniacal odour and a tendency to the deposition of triple phosphates, the drugs are of a different character. Prominent amongst those of value is hexamethylenamine, which should be given in full doses, 10 to 20 gr., three times a day, except in the case of children, where it must be given with care; and its congeners, cystamin, hetralin, and the like. The balsamic drugs, such as benzoate of ammonia and soda, with boric acid and dilute mineral acids, are of value. A drug of great value, when the tendency to deposition of phosphates is very marked, is the acid phosphate of sodium in full doses of 30 to 40 gr. in 3 or 4 oz. of water, repeated every four hours or so. Sandalwood oil without the alkalies will be found of service in such cases.

Treatment by Bladder Washes and Instillations.—In the most acute stages it is best not to use any form of bladder washing by means of the catheter, and to rely

upon the methods already indicated; but as the extreme symptoms subside the cure may be accelerated by washing out the bladder with various lotions. The best of these is perhaps silver nitrate solution in very weak strengths.

The bladder should first of all be washed out with boiled water through a No. 10 or No. 12 soft rubber catheter. The eye of the catheter should be large and smooth, and the instrument should be passed with great gentleness. When, owing to prostatic enlargement, there is difficulty in passing the soft catheter, a silk-web coudé catheter of the same calibre should be employed, or sometimes a fully curved metal catheter will be found to meet the difficulty. Whatever instrument is used the greatest gentleness should be exercised, and if spasm of the compressor urethræ muscle hinders the passage of the instrument, it should be combated by the injection of a few drops of a weak cocaine or eucaine solution into the bulbous urethra. A solution of 2 per cent cocaine or 4 per cent eucaine is usually quite sufficient. Novocain can be used in rather greater strength, 4 to 8 per cent, as it is decidedly less toxic than cocaine or eucaine.*

The boiled water is used for its mechanical properties, to wash away the tenacious mucopus and to allow the astringent and antiseptic solution which follows to exert its full effect upon the bladder walls. Two drachms of bicarbonate of soda to the pint of boiled water is often of service in dissolving the mucopus and cleansing the bladder preparatory to the use of the antiseptic washes. The bladder should be washed until the water comes back clear, and usually one or two pints will be needed for this purpose. It is better to use a smoothly working four- or six-ounce syringe, made of glass or metal, with an asbestos or metal piston, with which to give this lavage. These instruments can be boiled, and the irrigation can be better performed than with the irrigator, or funnel and tube. If preferred, a two-way catheter can be used, but the total calibre of this instrument must be considerably larger, to allow of free ingress and egress of the fluid. Distention of the bladder must stop just short of pain. The bladder having been washed clean, a pint or more of the antiseptic solution should be used.

There are many excellent drugs for this purpose, but the most successful is silver nitrate, in the strength of 2 to 4 gr. to the pint of distilled water to commence with, and increased daily by 1 gr. to the pint until the strength of 10 gr. to one pint is reached. Some patients are much more tolerant than others of this drug, and the strength must be suited to the exigencies of each case.

Lysol $\frac{1}{2}$ to 1 per cent, oxycyanide of mercury 1-10,000 to 1-2000, carbolic acid 1-500, protargol $\frac{1}{2}$ per cent, are all useful. After the use of these drugs the bladder should be washed clean again with boiled water, and a few ounces of the latter allowed to remain.

A recent and very useful, but expensive, drug is argyrol. This should be used in a somewhat different manner. It is practically painless, and after the preliminary washing of the bladder, 2 or 3 oz. of a 5 or 10 per cent solution should be injected into and allowed to remain in the bladder.

Peroxide of hydrogen is often very useful as a bladder wash in strengths of one or two ounces to the pint of water, the 20-volume peroxide of hydrogen being employed. It should not be used where much pus is present, as much gas is evolved in the bladder in such cases, giving rise to painful and troublesome distention; but if the pus is first washed away by lavage with sterile water, the peroxide solution can then be used with safety.

Treatment by Operation.—As a rule operation is not required in acute cystitis. In a few cases, however, the inflammation is of the most acute and fulminant type, and within a day or two of the onset of the attacks, sloughs of the vesical mucous membrane come away with the urine, mixed with blood and pus. Pain, frequency of micturition, and tenesmus are acute, and the usual remedies appear

* Sudden death has followed the introduction of cocaine into the urethra.—AMERICAN EDITOR.

to have little or no effect. In such cases the bladder should be thoroughly drained by a suprapubic cystotomy (*vide infra*), and constant irrigation should be instituted.

Subacute Cystitis.—As a rule subacute inflammation of the bladder is the sequel and the closing stage of acute cystitis, but in some cases the inflammatory condition is subacute from the commencement of the illness.

The symptoms differ only in degree from those of acute inflammation. The frequency is much less marked, pain is not nearly so severe, and hæmaturia is very rarely noted.

TREATMENT is carried out upon the same lines as that of acute cystitis, but intravesical medication may be commenced at once by means of irrigations and instillations through the catheter. Urinary antiseptics and sedatives should be given by the mouth, and it is not necessary to confine the patient absolutely to bed.

Chronic Cystitis.—It is convenient and practical to classify chronic inflammation of the bladder as *Simple*, *Gonorrhœal*, and *Tuberculous*, the first class comprising for convenience all cases of cystitis not due to the gonococcus or tubercle bacillus.

1. *Simple Chronic Cystitis.*—This is seldom met with except as a result of some further disease of the urinary system.

Obstructions to micturition in the form of stricture or prostatic enlargement, trophic changes due to disease of the central nervous system, and constant reinfection from above from a pyelitic or pyelonephritic kidney, are all common causes of a chronic cystitis, whilst vesical calculus is always accompanied by a more or less chronic inflammation of the vesical mucous membrane. But in some cases a chronic cystitis may persist without any of these contributory causes, having as its starting-point enteric fever, pneumonia, influenza, or some general infection of a bacterial character.

A very large proportion of cases of chronic cystitis, arising and persisting without any apparent exciting cause, are found to be due to the presence of bacilli belonging to the coliform group, either alone or in combination with staphylococci. These infections of the bladder by *Bacillus coli communis* are exceedingly intractable, and tend to relapse again and again after apparent cure. In addition to the use of the local measures advised below, the use of a vaccine prepared from the patient's own bacilli in many cases gives great assistance; but so intractable are these forms of chronic cystitis that a very guarded prognosis as to complete cure should always be given.

TREATMENT.—As chronic cystitis is in the great majority of cases dependent upon some other condition for its persistence, the treatment must in the first instance be directed to a removal of the cause. The removal of stone from the bladder, the cure of a tight stricture, or the removal of an enlarged prostate, are commonly followed by the cure of the chronic inflammation of the vesical mucous membrane, and the reader is directed to the sections dealing with these subjects for instruction in their treatment.

But sometimes, as already mentioned, no contributory cause can be discovered, and in these cases the chronicity of the infection appears to be due to the imperfect power of resistance of the patient to the particular pathogenic organism. Here the usual local measures must be adopted, consisting of intravesical medication with the various urinary antiseptics, and the patient's general health must be fortified by a generous diet, ample supply of fresh air, and freedom, where possible, from over-fatigue, worry, and anxiety. In these cases the treatment by mineral waters is sometimes exceedingly efficacious, and the choice of a spa should be determined by the alkaline or acid nature of the cystitis. For the former, Bad Wildungen in Germany has for many years had a high and

deserved reputation, whilst in cases where the gouty or uric acid diathesis is marked, and the chronic cystitis is always of an acid character, the waters of Contrexéville and Aix-les-Bains often exercise an exceedingly beneficial influence. The question of serum-therapy and vaccines is considered in the section upon tuberculous cystitis (*vide infra*).

2. *Gonorrhœal Cystitis*.—In by far the greater number of cases, gonorrhœa, fortunately, does not attack the bladder; indeed, in many instances the infection travels no higher in the urinary tract than the bulbous urethra. But when the gonococcus gains access to the urethra behind the compressor urethræ muscle, the prostatic mucous membrane, the prostatic follicles, and the mucous membrane of the neck of the bladder become infected. Gonorrhœal infection of the bladder of an acute nature occurs in some cases, and when the acute symptoms have subsided, a chronic infection is sometimes left behind, which usually is limited to the neighbourhood of the trigone and orifice of the bladder. The gonococcus appears to possess an extraordinary vitality and to be able to remain hidden, probably in the crypts and follicles of the prostate, for almost indefinite periods, causing repeated relapses after perhaps long intervals of apparent cure in cases where there has been no possibility of reinfection.

This lurking of the gonococcus in the recesses of the prostate and seminal vesicles undoubtedly explains the constantly recurring attacks of gonorrhœal inflammation of the neck of the bladder, and chronic gonorrhœal cystitis cannot be considered apart from infection of the prostate and seminal vesicles.

The diagnosis of gonorrhœal prostatocystitis having been made, careful and prolonged treatment is necessary, and the treatment of the cystitis must be considered together with that of the urethroprostatic infection. Thus the anterior urethra must be treated by the appropriate measures; all strictures, granular patches, infiltrations, and infected glands of Littre must receive due attention.

The treatment of the prostatocystitis consists of instillations and irrigations, combined with the emptying from the prostatic follicles and seminal vesicles of their infected contents by means of rectal massage.

Posterior irrigation should be given by what is usually known as Janet's method. An irrigator can, holding 2 pints or more, with eight or nine feet of rubber tubing, and a conical glass nozzle which will fit the urethral meatus, is all the apparatus that is required. The patient empties his bladder, and the anterior urethra is well washed out with boiled water.

In most cases it is well to inject into the bulb about 30 min. of a 2 per cent solution of novocain. The patient holds this in by compressing the meatus with his fingers for a moment or two. By stripping the solution along the urethra in a backward direction, the surgeon can then force it into the bulb, and by further backward pressure of the fingers upon the bulb, pressing the latter against the arch of the pubes, the solution can be forced into the membranoprosthetic urethra through the compressor urethræ. In this way the mucous membrane of the bulb and deep urethra is cocainized. If preferred, this injection may be given by a Guyon's syringe, the little bulb of which is passed down into the deep urethra, and the fluid injected. The object of this anæsthesia is to obviate spasm of the compressor urethræ, which sometimes prevents the free flow of the irrigation into the bladder.

The patient lies on a couch with the irrigator suspended about five or six feet above him. The nozzle is then introduced into the meatus, and the fluid allowed to flow very gently until the whole anterior urethra is ballooned, when, the pressure being gradually increased, the compressor gives way, and the fluid is felt to pass along the urethra and flow into the bladder, the fingers holding the penis feeling a distinct thrill. Deep inspiration and expiration by the patient materially assist this proceeding. As soon as a desire to micturate is felt, the

irrigation is stopped, usually when about 10 or 12 oz. of solution have been used. The patient is then placed in the knee-elbow position, and the contents of the prostate and seminal vesicles are expressed by rectal massage. The patient then stands and empties the bladder.

This irrigation should be given each day for about ten days to a fortnight. The best solution to employ is permanganate of potassium, commencing with a strength of 1-5000 and increasing to 1-1000 or 1-500. It must not be forgotten that in these cases the infection is usually a mixed one, and although the gonococcus responds very readily to this solution, other pus-producing organisms may be present, and in these cases, after a rest of a week or so, a further course of irrigation should be given every other day for a fortnight with perchloride of mercury solution, commencing with a strength of 1-20,000 and increasing to 1-15,000 or 1-10,000. Perchloride of mercury is exceedingly irritating to the bladder, and the weaker strengths will therefore be advisable. Oxycyanide of mercury will be found of great value where a mercurial preparation is indicated. It should be used in strengths of from 1-10,000 to 1-2000. It is decidedly less irritating than perchloride or biniodide of mercury.

In those cases where erosion and ulceration of the posterior urethral mucous membrane are present, instillations of a few drops of strong solutions of silver nitrate, copper sulphate, or zinc sulphate often prove exceedingly useful, whilst argyrol in solutions of 10 to 30 per cent has latterly proved of great service. These instillations are given either through a fine catheter or by means of a Guyon's deep urethral syringe. This is passed well through the compressor urethræ, so that the eye lies in the prostatic urethra. The fluid is then injected, and flows over the prostatic mucous membrane and the neck of the bladder, which should be emptied before the injection is given. Sometimes direct applications to the deep urethra are required, and these must be given through the tube of a urethroscope. (See also GONORRHOEA.)

3. *Tuberculous Cystitis*.—Once the diagnosis of tuberculosis of the bladder is made, the prognosis should be most guarded, even when the area infected is but small, and, so far as the surgeon can judge, is confined to the bladder. When extensive infection of the bladder is already established, with or without tuberculosis of other parts, the prognosis is grave indeed, for the writer cannot bring forward a single case which can be called a permanent cure, though much can be done to ameliorate the condition of even advanced cases.

Even when, under treatment, a patient has apparently lost all symptoms, when micturition is normal and painless, the urine clear and bright, and tubercle bacilli have not been present in the urine for many months, a too favourable prognosis as to immunity from trouble in the future should be carefully guarded against. For tuberculosis of the bladder is marked by the same phenomena of apparent cure and certain relapse as in the lymphatic glands, the lungs, and joints, the intermittency of the disease being one of its most marked characteristics.

Treatment of tuberculous cystitis by operation has almost ceased, and in our opinion, most rightly. Simple drainage of the bladder, either by the perineum when the disease is limited to the vault of the bladder, or suprapubically when the base alone is infected, has been practised, upon the theory of giving rest to the bladder as, for instance, rest is given by fixation of a joint in early tuberculous arthritis. But unfortunately drainage opens the way for the almost inevitable introduction of septic organisms, and the addition of sepsis to a tuberculous bladder may be likened to applying fire to tow.

Scraping of the evident tuberculous patches through a wide suprapubic cystotomy, and under the guidance of a strong light thrown upon them through a speculum, has the disadvantage that only the obvious patches are treated,

and the miniature and early tubercles remain to mature in their turn. Indeed, the history of surgical intervention in tuberculous cystitis is one long tale of failure, and it must not be forgotten that the sinuses left by operation frequently become tuberculous, and the urine which was previously acid may become alkaline when infected with other organisms, and phosphatic crusts tend to form and adhere to ulcerated patches and to the wall of sinuses established by operation.

When sepsis has been added to a pure tuberculous infection by improper and dirty catheterism—and by this is not necessarily meant gross surgical uncleanness, but slight neglect of the stringent aseptic precautions necessary in catheterizing these cases—drainage and thorough irrigation of the bladder may certainly give some relief and remove the more distressing symptoms; but the relief is limited to the sepsis, and cannot be expected to cure the tuberculosis.

Irrigations of, and instillations into, tuberculous bladders meet with no more success from a curative point of view than direct surgical operations, except in so far as they tend to clear up a septic element which may complicate the case. And bearing in mind the ease with which a tuberculous bladder can be infected with organisms of suppuration, it is advisable to limit catheterism and instrumentation generally to the necessities of diagnosis and the relief of retention of urine. But although the surgical treatment of tuberculous cystitis has to be painted in such dull colours, within the last few years its treatment by inoculation has been attended with some success, and in cases where the infection is not of long standing, and is fairly limited in extent, some apparent cures have resulted.

The present treatment of tuberculous cystitis by tuberculin injections is based upon the work of Prof. Sir A. E. Wright upon opsonins, and is controlled by examination of the tuberculo-opsonic index.

The preparation employed is the tuberculin R. of Koch, which is an emulsion of the dead bodies of tubercle bacilli, sterilized by heat. The theory upon which the treatment depends is that the tuberculin produces in the blood serum certain substances (opsonins) which act upon the bacilli in such a way as to render them a more easy prey to the leucocytes (phagocytes) of the patient's blood. Briefly stated, after an injection of tuberculin R. the phagocytic powers of the leucocytes show a decrease for a certain period, followed by a definite increase. The former is called the negative phase, the latter the positive phase. If during the negative phase another injection is given, the negative phase is deepened, and consequently harm is done instead of good; but if the second injection is given towards the end of the succeeding positive phase, the following negative phase is smaller than the first negative, and the next positive phase is higher than the first. Stated in terms of a chart, for instance a temperature chart, the gradual rise of opsonic power follows very much the course of the rise of temperature in a typical case of typhoid fever.

Now, if this be true, it is obvious that numerous estimations of the opsonic index must be undertaken to prevent injections being given at too frequent intervals, i.e., during the negative phases, and so causing a cumulation of negative results. But in the treatment of tuberculous cystitis by tuberculin, two facts emerge from clinical observation: (1) The period between injection and the summit of the positive curve which ensues upon the negative one is fairly constant in any given patient. Therefore, after the first injection, if by several estimations of the opsonic index the period of maximum intensity is found to be from fourteen to twenty-one days, it is fairly safe to interspace the doses by that period. (2) In common with several other observers, the writer (struck with the lamentable failure of surgical measures) treated a considerable number of cases with tuberculin R. some years prior to the publication of Wright's

work upon opsonins, and observed that too large a dose or too frequent a dose was followed by a clinical negative phase, i.e., that frequency of micturition, pain, and hæmaturia were all increased by over-dosage or too frequent administration; in these cases the doses were regulated entirely by the clinical signs, and results were obtained very little inferior to those obtained by estimations of opsonic indices. In a small number of cases apparent cures were noted, but, bearing in mind the strong tendency to partial spontaneous cure, and to periods of immunity from symptoms, it is not wise to place too great a reliance upon the permanence of these cures.

Still, it appears to be safe to use injections of tuberculin R. at intervals suggested by an estimation of the period required in the case of the first dose to bring the index to its positive maximum, controlled thereafter by the clinical symptoms and the effect of successive doses upon them. This is a most important point in the tuberculin treatment of tuberculous cystitis, for the continual estimation of the opsonic index is by present methods entirely out of the scope of the general practitioner, requiring much time and considerable acquaintance with the methods of bacteriological research. Even in advanced cases, a certain amount of improvement and some relief of the most distressing symptoms have been noted; and to sum up the matter, the writer has found more success to follow inoculation with tuberculin R. than has attended any operative or local treatment.

In cases where the bladder is constantly receiving infection, either from the kidneys above or from the genital system below, surgery has, however, to be called to the patient's aid. Thus, if the patient's condition permits, a tuberculous testis, vas deferens, and seminal vesicle should be removed entirely.

In the event of renal tuberculosis being the origin of the bladder infection, the question of nephrectomy entirely depends upon the condition of the opposite kidney. If the latter is healthy, the wisest course to pursue is to remove the diseased kidney by a lumbar nephrectomy, and by prolonging the incision downwards and forwards, to remove the corresponding ureter as close to the bladder as possible. It is in this connection that the value of expert cystoscopy has been so strikingly manifested, for by it alone, or combined with ureteric catheterization and intravesical separation of the urine, can the condition of the presumably sound kidney be ascertained. It should therefore be an axiom of modern surgery that a nephrectomy for tuberculosis of the kidney should never be undertaken until after careful cystoscopy and separation of the urine from the two sides, either by ureteric catheterization or intravesical separation.

These surgical measures should be followed by a course of injections of tuberculin R. to deal with the secondary infection of the bladder.

GENERAL TREATMENT of patients suffering from tuberculous cystitis follows well-recognized lines. Just sufficient exercise should be permitted to keep the patient's general health in good order. Cod-liver oil, malt, and fattening foods are indicated, but alcohol should be diminished, and, wherever possible, entirely prohibited. The bowels should be regulated by mild aperients and, if necessary, enemata. The diet should be easily assimilable and generous. Fresh air, warmth, and avoidance of fatigue and chill are very necessary.

Drugs as a rule have very little effect upon the course of the disease, though pain and frequency of micturition may be relieved somewhat by the use of urinary sedatives. Of these the most efficacious is perhaps the oil of yellow sandalwood, in doses of 10 to 15 min. three times a day. In the case of patients who are unable to assimilate this somewhat nauseous drug gastro-intestinal irritation is caused by it, evidenced by dyspepsia, nausea, and sometimes a skin eruption. These effects are less likely to ensue if care is taken to obtain only fresh oil of the purest quality.

Henbane in full doses, i.e., $\frac{1}{2}$ to 1 dr. of the tincture, sometimes relieves the pain and frequency, whilst decoction of tritium repens, taken in doses of 4 to 6 oz., makes the urine somewhat more bland and less irritating.

In the later stages of the disease, when a cure is evidently not to be hoped for, opium is the only drug to give relief, and it is neither necessary nor desirable to refuse it. In the form of suppositories of morphia, or by hypodermic injection, it does something to soothe the really acute pain and distress of the closing scenes of this most distressing malady.

John George Pardoe.

DACRYOADENITIS AND DACRYOCYSTITIS.—(See LACRYMAL APPARATUS, DISEASES OF.)

DANDRUFF.—(See SEBORRHOEA.)

DEAF-MUTISM.—(See EAR, DISEASES OF.)

DELHI BOIL.—These chronic ulcers are somewhat intractable. Copper sulphate solution, 1, 2, 3, or 4 gr. to the ounce of water, appears to expedite the cure. Escharotics must be avoided, as more scarring results if these are used. An ointment composed of equal parts of methylene blue, lanolin, and vaseline (Cardamati's ointment) has proved successful in a number of cases. Some prefer the application of a thin leaden plate over the ulcer, as the steady continuous pressure exercises a beneficial effect. Others excise the ulcers: this expedites healing, but the scar may be greater. The results of treatment with salvarsan are variable, but in any case it is worth a trial. Row reports cases cured by injections of killed cultures of the causative organisms.

C. W. Daniels.

DELIRIUM TREMENS.—(See ALCOHOLISM.)

DENGUE FEVER.—There is no specific treatment. Hypodermics of morphia may be required if the pains are severe. Quinine is useless. Low diet and rest in bed are essential. The joint affections are often induced by too early exertion. Hot applications to the affected joints in the early stages give relief, and mild counter-irritants, such as painting with tincture of iodine or iodide of mercury, are useful in the later stages.

C. W. Daniels.

DENTAL CARIES.—(See TEETH, CARIES OF.)

DERMATITIS HERPETIFORMIS.—Obviously, the most important thing in connection with this disease is the diagnosis, but assuming that this has been correctly made, the treatment now to be indicated is generally to some extent helpful in alleviating the patient's sufferings in a very obstinate disease. The most important remedy is rest, and admission to hospital almost always results, in the working classes, in the rapid disappearance of the disease, which, however, unfortunately reappears when the sufferers resume work. In the better classes the same result follows a sojourn in any health resort, with the same recurrence of the disease on the return to work. The longer the interval, however, the better the chance of the disappearance of the disease, or at least of the lightening of the severity of the attacks.

Internally, the best remedy is arsenic, which almost always controls the eruption. But it must always be taken under strict supervision, for its continued free administration is associated with grave risks. Ichthyol, strychnine, atropine, salicin, and many other drugs have been recommended; but none of them has the controlling power which arsenic possesses.

Of the many external applications, the most useful is the least likely, for it would not occur to any one to apply to so sore and inflamed a skin so rude a

preparation as sulphur ointment, and yet there is no remedy which gives such immediate relief from the itching. Ichthyol ointment is applied by some, and carbolic oil and other anti-pruritic applications may be tried. Another line of treatment is that suggested by Jas. C. Johnston. He believes the disease to be toxæmic in origin, and treats cases by the administration of calomel followed by enormous draughts of water. In the writer's experience this has proved a very valuable addition to other treatment of this intractable disease; and the worst case of the disease which has been under his care, and which defied all the ordinary methods of treatment, recovered and has remained almost free for two years years after heroically undergoing a fortnight of starvation.

Norman Walker.

DIABETES INSIPIDUS.—The hygienic treatment of this condition involves attention to the state of the skin, warm clothing, and the avoidance of chill and fatigue. The diet should be as far as possible free from salt and poor in nitrogenous constituents. It should consist chiefly of farinaceous foods, vegetables, and fruit, with a minimum of meat. The consumption of fluids should be restricted as far as the patient can stand it.

Treatment by drugs is very unsatisfactory. If there be a syphilitic history, iodide of potash should be given. Of the many drugs which have been tried the following are the most likely to be of help: Fluid extract of ergot (1 to 2 dr. three times a day); opium up to the limits of tolerance; gallic acid (up to 40 gr. a day) alone or combined with opium; valerian in very large doses (probably most useful in hysterical cases). Suprarenal preparations have not proved encouraging.

Robert Hutchison.

DIABETES MELLITUS.

Dietetic Treatment.—Having determined, by the permanent presence of sugar in the urine, that one has to deal with diabetes and not with a mere glycosuria, one must next ascertain, by means of the perchloride of iron or other test, whether any acetonæmia exists. Assuming this to be absent, the next step is to decide as to the severity of the particular case in hand. For this purpose a "test diet" should be given, consisting of meat, eggs, green vegetables, butter, and 4 oz. of white bread, part of the latter being eaten at each meal. The amount of sugar in a mixed sample of the urine should be estimated after the lapse of three days, and if it contains less than 70 grams of sugar in the twenty-four hours (which is the amount yielded by the starch in 4 oz. of bread) one has to deal with a mild case in which there is a certain tolerance of carbohydrates. If, on the other hand, the amount of sugar excreted be more than 70 grams, then the case is a severe or "composite" one, with no tolerance of carbohydrates, and in such a case it will often be found that acetone is present in the urine as well as sugar.

The subsequent regulation of the diet must be determined by the particular class of case to which the patient belongs. If he can take 4 oz. of bread without glycosuria resulting, one must go on adding bread to the diet until one finds the limit of his tolerance, and then keep him on a diet containing rather less than that amount, or its equivalent in some other form of carbohydrate-containing food (see Table below), for it is never safe to allow a diabetic to take starchy foods up to the limit of his powers of assimilation. The patient should adhere to this diet, provided his weight remains satisfactory, for some weeks, when the amount of starch may be cautiously increased, a watch being kept for any return of glycosuria. If, on the other hand, the case be one of the severe or composite type, in which sugar is excreted even upon a carbohydrate-free diet, it will be necessary to restrict the intake of proteins as well as that of carbohydrates, for in such a case sugar seems to be derived from the proteins too.

Eighteen ounces of cooked meat, or its equivalent in some other form of protein food, should be the limit allowed in such a case. The writer's own practice is to give 6 oz. of meat, 3 eggs, 4 oz. of casoid bread, and 2 pints of sugar-free milk (see below), along with green vegetables and butter. If the sugar excretion does not fall, or if the patient loses weight, a known quantity of ordinary bread is added to the diet.

Should the perchloride of iron test show the presence of aceto-acetic acid in the urine, it is not advisable to put the patient on a quite strict diet, certainly not at once. One should proceed cautiously in the reduction of the carbohydrates, administering bicarbonate of soda meanwhile.* The further treatment of such cases will be considered later on.

It will be evident from these considerations that there is no uniform "diabetic diet." Each case must be treated on its own merits.

In arranging the details of the diet the following tables will be found useful :

I. FOODS WHICH YIELD LITTLE OR NO SUGAR.

All animal foods (except liver, sausages, cheese, cream, and oysters).

All clear soups.

Unsweetened jellies.

Green vegetables, but not peas, beans, or lentils.

Asparagus, celery, young rhubarb, tomatoes, cucumber, and mushrooms.

All nuts (except chestnuts); early oranges, apricots, strawberries, and gooseberries.

II. TABLE OF CARBOHYDRATE EQUIVALENTS.

Two oz. of bread =	2 oz. of pea or lentil flour
" " "	$1\frac{7}{10}$ oz. of rice
" " "	$1\frac{1}{2}$ oz. of oatmeal or barley flour
" " "	$1\frac{3}{8}$ oz. of cornflour, arrowroot, sago, tapioca, or rice
" " "	10-15 oz. of the sweeter fruits
" " "	40 oz. of apples

Use of Special Articles of Food:—

Bread.—No completely satisfactory substitute for bread in the dietary of diabetes has yet been found. The best are those which contain casein.† Gluten breads (e.g., Brusson Jeune) are almost never really free from starch, and are not suitable when a strict diet is being observed. The Cheltine and Manhu breads also contain large quantities of starch, and toast, though often ordered for diabetics, is quite inadmissible for the same reason. A variety of cakes and biscuits prepared from cocoa-nut, almond flour, bran, aleuronat, roborat, and other ingredients are made by the makers of special foods for diabetics, and serve to introduce variety into the diet.

Milk.—The sugar of milk is less harmful to diabetics than most other forms of carbohydrate, but there are few in whom it does not aggravate the glycosuria. Cream, however, is permissible in most cases, unless a very strict diet is being enforced. A special milk, entirely free from sugar, has been prepared under the writer's directions, and can be obtained in a sterilized form from Messrs. Callard, Regent Street, W. It can be given diluted with soda water, or flavoured with tea or coffee, or made into custards with eggs, and will be found of great assistance in many cases.

Fatty Foods are of the greatest use in diabetes; butter, cream, cream cheese, bacon, ham, and salad oil being the best forms.

Vegetables.—Green vegetables contain so little starch that they may be allowed in every case. They should be taken with melted butter. Asparagus, celery,

* The temporary appearance of acetone in the urine in a mild case of diabetes, when first put upon strict diet, is of no significance, and will pass off after a week or two. Meanwhile alkali should be given.

† Such breads are supplied by The Protein Co., Welbeck Street, W., Callard & Co., Regent Street, W., Bonthron & Co., Glasshouse Street, W.

young rhubarb, tomatoes, vegetable marrow, cucumber, and mushrooms are also harmless.

Potatoes are not permissible in cases in which a strict diet is being enforced. If a limited quantity of carbohydrate can be taken they are a useful food, as they can be made to absorb so much fat; 6 oz. of cooked potato may be reckoned as the equivalent in starch of 2 oz. of bread. In some cases the starch in potatoes seems to be better tolerated than that in bread.

Fruits.—Most fruits are not permissible, but early oranges, apricots, strawberries, and gooseberries may be taken in moderation. Nuts of all sorts, except chestnuts, are allowed, and are of great value to the diabetic on account of their richness in fat.

Lævulose, or fruit sugar, is fairly well assimilated in some cases of diabetes, and may be given a trial in quantities of 1 or 2 oz. per day. It is rather expensive.

The following table, which shows (approximately) the percentage of carbohydrates in some of the commoner foods, may be of help in making a selection :

APPROXIMATE PERCENTAGE OF CARBOHYDRATES IN SOME FOODS.					
<i>Milk Products.</i>		Carrots	10.0	Leeks	5.8
Cow's milk	4.5	" (cooked)	3.0	Tomatoes	5.0
Butter-milk	3.3	Turnips	5.0	Vegetable marrow	
Koumiss	1.5	" (cooked)	0.6	(cooked)	0.2
Cream	3.0	Radishes	4.6		
Devonshire cream ..	1.5	Beetroot	11.0	<i>Fruits.</i>	
		" (cooked)	2.8		
<i>Cereals.</i>		Parsnips	14.0	Apples and pears ..	12.0
White bread	50.0	" (cooked)	1.4	Stone-fruits	10 to 15
Oatmeal and rolled		Artichokes	14.6	Gooseberries (ripe) ..	9.0
oats	65.0	" (cooked)	4.6	" (green)	2.0
Rice	76.0	Onions	6.3	Currants	8.0
" (boiled)	40.0			Strawberries	6.0
		<i>Vegetables.</i>		Raspberries	5.0
		Cabbage (cooked) ..	0.4	Cranberries	4.0
Green peas	16.0	Sprouts	3.4	Grapes	15.0
Dried "	55.0	Lettuce	2.6	Melons	7.0
French beans	7.0	Spinach (cooked) ..	0.8	Bananas	22.0
Revalenta	65.0	Water-cress	3.7	Oranges (ripe)	8.9
Soy beans	28.0	Cauliflower	4.7	" (young)	2.0
Peanuts	17.0	Asparagus	2.9	Pineapples	9.5
		Cucumber	2.1		
<i>Roots and Tubers.</i>		Rhubarb	2.3	Nuts	9 to 12
Potatoes	20.0	Celery	3.3	Almonds	10.0
				Chestnuts	40.0

Beverages.—Malt liquors, sweet wines, and sweetened aerated drinks must be avoided, also liqueurs and cordials made with sugar. On the other hand, spirits and all natural wines are allowable, and should form part of the regular dietary of diabetics, as alcohol aids in the digestion of fat, besides replacing sugar to some extent. Harvey's sugar-free ale (Grove Brewery, Luddenden Foot, S.O.) is a pleasant and harmless drink for patients who like malt liquors. Fremlin's old English ale is also nearly sugar-free.

Tea and coffee may be allowed freely; pure cocoa extract contains so little starch that it also is permissible.

As diabetics are apt to suffer from hunger, at least four meals should be allowed in the twenty-four hours. It is safest to make any change in diet gradually, especially if acetone be present in the urine.

Hygienic Treatment.—The diabetic should be warmly clothed, and should avoid chill, over-exertion, and worry. Muscular exercise is useful, but must always stop short of fatigue. Care should be taken to have a daily action of the bowels. If acetone be present in the urine, special precautions should be

taken to avoid the onset of coma. Any sudden change of habits (e.g., confinement to bed), any fatigue (e.g., a long railway journey), or chill, is then specially dangerous.

Drug Treatment.—Opium is the drug from which most benefit is likely to be obtained. It may be given either in the form of the extract or of crude opium, $\frac{1}{2}$ gr. of the former or 1 gr. of the latter being given as a pill after each meal, and the dose gradually pushed up to the limit of the patient's tolerance. If constipation prove troublesome, 1 or more gr. of extract of cascara may be added to each dose. Codeine is probably less useful than opium, but is preferred by some. It may be given in the form of the phosphate as a pill, beginning with a dose of $\frac{1}{2}$ gr. and gradually increasing it.

In the milder cases salicylate of sodium is sometimes useful : it may be pushed until 60 gr. are taken daily. Acetyl-salicylic acid, given in similar doses in a little water to which a drop of lemon-juice has been added, suits some patients better. Both should be avoided in cases with renal disease. Other drugs such as uranium nitrate (1 to 5 gr. of the nitrate well diluted), yeast, pancreatic extract (e.g., Holadin capsules), calcium iodide (4 gr. in solution, thrice daily), and arsenic (liq. acidi arsenosi up to 10 min. thrice daily) have been recommended at various times, but none of them can be depended upon. It may be said with confidence, indeed, that no drug exerts any real influence in the severe form of the disease, and that strong drugs should be administered only for a few weeks at a time, as they soon lose their effect.

Treatment of Cases in which Acetone is present in the Urine.—If the urine gives a well-marked perchloride of iron reaction, the administration of alkalis should be begun at once. The following is a useful prescription (Langdon Brown):—

R Sodii Bicarbonatis	3j	Magnesii Carbonatis	gr iij
Potassii Citratis	gr xxx	Aquam	ad 3j
Calcii Lactatis	gr iij		

Three times daily or oftener as required.

The reduction of the carbohydrates in the diet should proceed very gradually in these cases, but it is a mistake to be so afraid of coma as to make no attempt to reduce the glycosuria at all. Should any of the earlier symptoms of acidosis or threatening coma (e.g., headache, vomiting, abdominal pain) supervene, the amount of carbohydrate in the diet must be increased immediately. It is in the control of acetonuria that the so-called "oatmeal-cure" is sometimes useful. It is in no sense a cure for diabetes, and is only to be used in cases in which the glycosuria has first been reduced to as low a level as possible by the ordinary rules of diet. It is not suitable for very severe cases, and should not be repeated oftener than once every three weeks. The "cure" should be preceded by three days of a diet consisting only of green vegetables, fat bacon, butter, and about five eggs, along with tea, coffee, and alcohol; then for three days 8 oz. of oatmeal in the form of porridge or oatake are given, along with 4 oz. of butter and five eggs, with tea, coffee, and alcohol. This must be followed by another day of the "vegetable" diet before the patient returns to his ordinary "strict" diet.

The oatmeal diet may be combined with the vegetable diet, the essential feature being to allow no other form of carbohydrate on the oatmeal days. It is scarcely possible to carry out the oatmeal cure satisfactorily unless the patient is under treatment in a home or sanatorium; and many English patients, at all events, are inclined to regard such a "cure" as being on the whole worse than the disease.

In the worst cases of acetonuria of all, in which any attempt to restrict the intake of carbohydrates brings on threatenings of coma, there is nothing to be

done but to allow carbohydrates freely. In such cases, however, a day's starvation about once a week, on which day the patient is kept in bed on a diet of tea, broth, and alcohol, is often helpful in delaying the onward progress of the case.

Treatment of Complications.—If coma threatens, the diet should be reduced to skimmed milk and Vichy water, with preparations of oatmeal. Alcohol should be given freely in a dilute form; the bowels should be opened by enema followed by castor oil. Bicarbonate of soda should be pushed (a level teaspoonful every hour) both in liquids and in the form of enemata (1 oz. to $\frac{1}{2}$ pint of hot water), or preferably by the continuous introduction of a 3 per cent solution by the drop method; it cannot be given subcutaneously in sufficient quantity to be of any use. If coma be already present, three pints of a 2 per cent solution of bicarbonate of soda may be injected into a vein.*

Give antipyrin for headache; oxygen inhalations for dyspnœa; and brandy, digitalis, and ether (subcutaneously) for heart failure.

If phthisis, eczema, boils, carbuncles, or gangrene occur in the course of diabetes, the treatment of the main disease must be energetically carried out, and the local complication dealt with on the lines laid down in the special article relating to it. (See PHTHISIS, CARBUNCLE, etc.)

Pruritus vulvæ is often a troublesome complication. Besides the treatment recommended in the special article relating to that condition, lotions and vaginal injections containing a tablespoonful of fresh yeast to two pints of water, used twice a day, are helpful, but sometimes it may be necessary to have recourse to the catheter.

Robert Hutchison.

DIARRHŒA, ACUTE.

The treatment of acute catarrh of the bowel involves, in severe cases, rest in bed, especially if there be any fever or great weakness. The simplest diet is the best, such as equal parts of milk and lime-water, or milk whey. If the stomach is very irritable, only small quantities ($\frac{1}{2}$ to 1 oz.) should be given; and if a stimulant is needed, iced champagne should be tried. After the diarrhœa and pain have disappeared, a little solid food can be added; but hot drinks should be cautiously administered, as they may bring back the purging. Bland animal food is often better tolerated than starchy food; for example, cold chicken broth or chicken jelly, and baked or boiled custard puddings, are preferable to gruels or invalid foods made from cereals. But as convalescence progresses, ordinary simple diet may be allowed, care being taken that it is bland and well cooked; if the teeth are defective, it must be minced or pounded.

With respect to drugs, some prefer to commence treatment by administering $\frac{1}{2}$ oz. to 1 oz. of castor oil, but frequently when the case comes under notice the whole of the original contents of the intestine have been evacuated, and the indication is to check peristalsis and relieve pain. For this purpose we may employ bismuth, with alkalies and opium or morphine, as in the following mixture:—

R Bismuthi Carbonatis		Mucilaginis Tragacanthæ	℥xv
Sodii Bicarbonatis	āā gr x	Aquæ	q.s. ad 3j
Tincturæ Opii	℥viij		

Two tablespoonfuls every four hours.

In many cases the opium may be dispensed with, and simple *mistura cretæ* is all that is required.

In infectious diarrhœa, dilute sulphuric acid is useful in the treatment of adults, but it should be given freely, 12 or 20 min. in 1 oz. water every four hours.

* Sodium carbonate is more generally used.—AMERICAN EDITOR.

In cases of poisoning, severe pain often calls for the local application of fomentations to the abdomen and the use of morphine by hypodermic injection in sufficient doses to relieve the pain.

Where collapse occurs and the pulse is thready, $\frac{1}{2}$ pint to 1 pint of sterilized normal salt solution (0.75 per cent), at the temperature of the body, may be introduced under the skin of the flank.

Small iced-water enemata (1 to 2 oz.) are useful in the treatment of infantile diarrhœa, but should be repeated after each movement of the bowel.

Robert Saundby.

DIARRHŒA, CHRONIC.—As chronic looseness of the bowels may be due to several different causes requiring totally different treatment, the routine use of astringents is specially to be deprecated. This is not the place to consider in detail questions of differential diagnosis, but it should be pointed out that, as a necessary preliminary to treatment, a thorough investigation of the case is essential, embracing the stomach contents, a minute examination of the stools, both by the naked eye and the microscope, and (in many instances) an exploration of the lower bowel by the sigmoidoscope. Only thus can grave errors be avoided and right treatment instituted.

For purposes of treatment, cases may be divided into the following groups :—

1. **Gastrogenic**, in which the primary fault consists in mal-digestion in the stomach, the result usually of a deficient secretion of gastric juice in consequence of chronic gastritis or achylia.

2. **Pancreatic**, the result of a defective secretion of pancreatic juice or the blocking of the pancreatic duct. This form is characterized by white, greasy stools containing much undigested fat, and by great emaciation.

3. **Enteritis**, a catarrh of the small intestine, set up by badly-digested food, by irritants such as alcohol, by chronic infective processes, by chronic congestion the result of impeded circulation (e.g., in cirrhosis), by chill, etc.

4. **Colitis**, of which there are several varieties : (a) Chronic catarrhal colitis ; (b) Chronic ulcerative colitis ; (c) Colitis associated with new growths.

5. **Nervous**, in which the primary fault consists in an exaggerated irritability of the intestinal nerves. In some cases this shows itself in a tendency for the bowels to act immediately after a meal. These are sometimes spoken of as cases of *lienteric diarrhœa*. In others the action tends to occur upon any emotional excitement. Cases of so-called “morning diarrhœa” are probably due to the presence of a degree of chronic catarrh of the colon in a nervous subject.

The treatment must be modified according to the group to which the case belongs, but in all cases of chronic diarrhœa not due to gross organic disease, some common measures are applicable. In the first place, it is rarely possible to treat such patients in bed, although if that can be done it greatly lightens one's task. Rest in bed alone is indeed often sufficient to cause the looseness of the bowels to disappear, although unfortunately it is only too apt to recur when the patient returns to his ordinary habits. Still, it is sometimes of permanent benefit, and should always be insisted upon in very obstinate cases.

Diet can do much, but it is often necessary to individualize in drawing up the menu ; most patients, too, discover for themselves pretty quickly what articles are injurious. As a general rule, however, the following should be avoided :—

Fruits in any form, nuts, raisins, and currants.

Vegetables.

Whole-meal bread.

Oatmeal.

Honey, treacle, jams, marmalade.

Pickled and preserved foods, smoked meats or fish.

All sour things.

Soups.

Pastry.

Cheese.

Milk (unless well diluted).

All very hot or very cold liquids.

And the diet should consist of such articles as :—

White fish, roast or boiled meats, poultry, game, lightly-cooked eggs.

Stale white bread, toast, rusks, biscuits.

Mashed potatoes, boiled rice, macaroni, vermicelli, etc.

Jellies, custard, plain milk puddings.

Beverages :—Water, barley-water, peptonized cocoa, tea (lightly infused and not taken very hot).

Alcohol should be forbidden, or allowed only in strict moderation and well diluted. The food should be thoroughly chewed, and care taken that the teeth are in good order. It is important also to avoid chill, and a warm abdominal belt ("cholera belt") should be worn outside the under-vest in the winter at least.

We may now consider the special treatment required for each variety of chronic diarrhœa :—

1. *Gastrogenic*.—The special dietetic indication here is to reduce the amount of flesh foods, and only to give them finely minced or pounded. Peptonized milk may be used to replace them in part.

Dilute hydrochloric acid should be given in 15-min. doses after meals, with or without pepsin, or acidol tablets (two after each meal with half a tumblerful of water) may be found a more convenient way of giving acid. Acidol-pepsin pastilles are also obtainable. (See also *ACHYLIA*.)

2. *Pancreatic*.—In this variety the amount of fat in the diet should be reduced, and dextrinized or malted foods, e.g., Veda bread, Mellin's food biscuits, or grape-nuts, substituted for starchy products.

The place of the pancreatic juice should be supplied by a good artificial pancreas preparation, e.g., Holadin capsules (one or two about 3 hours after each meal). An active diastasic ferment may also be given with advantage immediately after any meal containing starch (taka-diastase, dia-malt, diazyme, etc.).

3. *Enteritis*.—The treatment of chronic catarrh of the small intestine is always a difficult matter, and such cases are amongst the most troublesome of all forms of chronic diarrhœa. There are no special dietetic indications beyond those suitable for chronic diarrhœa in general (see above). Alcohol must be strictly forbidden. Any co-existing disease (e.g., cirrhosis, renal disease, cardiac disease, phthisis, etc.) must be treated on the usual lines.

Chill should be guarded against with special care. Paradoxical though it may seem, such cases often do best with aperients, and a small dose of Carlsbad salts may be given in a tumblerful of hot water every morning. If, however, the diarrhœa be severe and persistent, it may be necessary to give astringents, the best being preparations of bismuth, calcium, and tannin, e.g. :—

R Bismuthi Carbonatis
Calci Carbonatis

Calcii Phosphatis āā pt. æq.

One teaspoonful three or four times a day.

R Tannigen or Tannalbin Tablets gr v

Two or more thrice daily.

Powdered cuttle-fish bone is also a useful astringent ; it may be given in 20-gr. doses three times daily.

For griping and flatulence, belladonna and menthol are the best remedies, e.g. :

R Mentholis	gr j	Extracti Gentianæ	q.s.
Extracti Belladonnæ	gr $\frac{3}{4}$		

Fiat pilula. Two or three times a day.

Great perseverance in treatment is required, as improvement is frequently slow. A course at a spa is often helpful in obstinate cases, Wiesbaden and Homburg being most suitable when there is deficiency of gastric secretion, and Carlsbad, Neuenahr, and Vichy when there is acidity.

4. *Colitis*.—*a. Chronic catarrhal*.—There is here no special dietetic indication beyond the rules already laid down for chronic diarrhœa in general. The most useful drugs are castor oil in small repeated doses (e.g., 10 min. in capsule or as an emulsion thrice daily), and bismuth (gr. xx. t.d.s.). It is often necessary to add a little opium, especially if tenesmus is troublesome; compound tincture of chloroform and morphine (B.P.) (5 to 10 min.) is a good form in which to give it.

Lavage of the bowel is often very helpful. One may use either hot normal saline (one or two pints), or a weak solution ($\frac{1}{2}$ to 1 per cent) of protargol or argyrol. (See also COLITIS.)

b. Ulcerative.—If ulceration of the colon be found on examination with the sigmoidoscope, much the best treatment in the writer's judgment is appendicostomy. (See COLITIS, SURGICAL TREATMENT OF.) If it be desired to try medical treatment first, details will be found in the article COLITIS.

c. Associated with New Growths.—Treatment here of course must be surgical. (See COLITIS, SURGICAL TREATMENT OF.)

5. *Nervous Diarrhœa*.—The general dietetic rules in these cases are the same as in all cases of chronic diarrhœa, but it is specially important to "individualize."

The best drugs on the whole are the bromides (e.g., sodium bromide gr. 12 night and morning), but it may be necessary at times to use opium to enable the patient to feel confidence in his bowel for some particular occasion. As far as possible, however, this should be avoided.

In cases of the lenteric type small doses of opium (3 min. of the tincture) before meals are useful, although some writers recommend small doses of Fowler's solution and nux vomica.

In the so-called "morning diarrhœa" to which reference has already been made, and which is sometimes very obstinate, no fluid should be taken after 6 o'clock in the evening, but the treatment otherwise is the same as for chronic catarrhal colitis. Sulphocarbolate of zinc (2½ gr. in pill thrice daily) has been recommended by some, and so also have small repeated doses of podophyllin (5 min. of the tincture (3.65 per cent) after meals). (See also DYSENTERY and SPRUE.)

Robert Hutchison.

DIARRHŒA, HILL.—In the more severe form this closely resembles sprue, and similar dietetic treatment is required, though it is not necessary to continue the treatment for so long a period. In the milder forms, a less severe regimen suffices. The Indian authorities advocate the administration of a drachm of liq. hydrarg. perchlor. (1-900) a quarter of an hour after food, and two hours later, 10 to 15 gr. of pepsin or ingluvin. If the disease does not readily yield to this treatment, the patient should be sent down to the plains. (See also SPRUE.)

C. W. Daniels.

DIARRHŒA, INFANTILE.—Diarrhœa may be acute or chronic.

Acute Diarrhœa may be *Catarrhal* or *Septic*.

Catarrhal Diarrhœa constitutes the ordinary simple form of looseness of the bowels to which all infants and young children are so liable. Infants during teething are peculiarly prone to this derangement, for teething sets up pyrexia, and a feverish child is more sensitive than another to changes of temperature.

An ordinary mild intestinal catarrh can be quickly cured by a dose of castor oil to clear away irritating matters from the bowel, followed by a mild astringent mixture. The latter must vary according to the nature of the evacuations.

If the stools are fermenting and acid, an alkali is required. The time-honoured chalk and catechu mixture may be given three times a day; or we may order instead—

R Bismuthi Carbonatis gr v | Pulveris Cretæ Aromatici (B.P. 1885) gr j

In a teaspoonful of glycerin and water three times a day.

Ordinary loose fæcal evacuations containing undigested curd of milk yield quickly, as a rule, to—

R Zinci Oxidi gr j | Glycerini ℥ x
Tincturæ Opii ℥ ¼ | Aquæ Carui q.s. ad ʒj

To be given every four hours, following, of course, the necessary aperient.

If, however, they persist, one grain of tannigen may be added to each dose. As alternative prescriptions we may employ :—

R Spiritus Ammonia Aromatici ℥ ss. | Glycerini ℥ x
Tincturæ Opii ℥ ¼ | Aquæ Anethi q.s. ad ʒj
Tincturæ Rhei Compositæ (B.P.) ℥ iij

Every four hours.

Or,

R Tincturæ Coto ℥ iij | Glycerini
Creosoti ℥ ¼ | Mucilaginis
Tincturæ Opii ℥ ¼ | Aquæ Carui q.s. ad ʒj

To be taken three times a day.

As long as the stools continue to show the presence of undigested curd, it is advisable to give from time to time a dose of castor oil or rhubarb and soda. At the same time the diet should be reconsidered, and, if thought desirable, the quantity of milk taken at each meal may be reduced, or one grain of citrate of soda may be added to each ounce of milk.

If the stools are foul-smelling, an antiseptic is required. Of these one of the best is a combination of one sixth to one third of a drop of tincture of iodine and glycerin of carbolic acid, a half to one drop, given in glycerin and water three times a day; or, if bismuth and chalk are being taken, one grain of salicylate of soda may be added to each dose of the mixture. As alternative remedies we may use :—

R Resorcini gr ij | Tincturæ Cardamomi Co. ℥ v
Tincturæ Rhei Compositæ (B.P.) ℥ iij | Aquæ Chloroformi ℥ x
Tincturæ Opii ℥ ¼ | Aquæ Menthæ Piperitæ q.s. ad ʒj

To be taken three times a day.

Or,

R Liq. Hydrargyri Perchloridi 1-900 ℥ v | Aquæ Chloroformi ℥ x
Tincturæ Opii ℥ ¼ | Aquæ q.s. ad ʒj

Three times a day.

Green stools, if acid, should be treated with the above bismuth remedy; if alkaline, they yield readily, as a rule, to a teaspoonful of a 2 per cent solution of lactic acid given every hour, or to two or three drops of dilute sulphuric acid given every four hours in a teaspoonful of water.

Whatever be the form of drug employed, it is useful to add to each dose a small quantity ($\frac{1}{5}$ to $\frac{2}{3}$ drop) of laudanum. The sedative delays the peristaltic movement of the bowel and gives the astringent a longer time to act. It is well, however, whenever an opiate is included in the prescription, to warn the attendants that the child is on no account to be waked up to take his medicine.

When the catarrh affects principally the lower bowel, the stools contain visible mucus in large quantities, with blood in patches and streaks from the straining. In this variety, which is often called "dysenteric diarrhœa," castor oil, opium, and ipecacuanha in small doses are especially indicated :—

R Olei Ricini	\mathfrak{M}_{ij}	Glycerini	\mathfrak{M}_x
Tincturæ Opii	$\mathfrak{M}_{\frac{1}{2}}$	Aquæ Cinnamomi	q.s. ad \mathfrak{Zj}
Vini Ipecacuanhæ	$\mathfrak{M}_{\frac{1}{2}}$		

To be given every four hours after food.

If in these cases the tenesmus is great and the bowel protrudes during defæcation, a local sedative is indispensable. One drop of laudanum in a teaspoonful of thin warm boiled starch must be injected into the bowel after a stool, or a suppository containing one-fifteenth of a grain of cocaine in five grains of cocoa butter may be used instead, and repeated twice a day.

In cases where the tenesmus is extreme and the prolapsed mucous membrane protrudes as a bright crimson ball, which cannot be retained within the sphincter even for a moment, the projecting part should be first fomented with warm water; then half an ounce of thin warm boiled starch, containing two drops of laudanum and five grains of powdered ipecacuanha, should be injected into the rectum, and the fundament be afterwards covered with a thick poultice of boiled starch. The enema may be repeated twice a day, but the fomentation and the poultice must be renewed after each action of the bowels.

The form of looseness called "lienteric diarrhœa" requires a different treatment. The looseness is due to exaggerated peristaltic movement of the bowels. The peristalsis is induced by the act of eating, and the stools are preceded by severe griping pains and marked by extreme urgency. An infant while taking his bottle stops sucking, cries in pain, and discharges the stool in a sudden gush. An older child has often to hurry away from the table during the course of a meal. This variety is quickly cured by small doses of arsenic and nuxvomica :—

R Liquoris Potassii Arsenitis	\mathfrak{M}_{ss}	Glycerini	\mathfrak{M}_x
Tincturæ Nucis Vomice	$\mathfrak{M}_{\frac{1}{2}}$	Aquæ Carui	q.s. ad \mathfrak{Zj}
Tincturæ Cardamomi Co.	\mathfrak{M}_v		

To be given three times a day.

The quantities must, of course, be made larger for older children, but the arsenic solution should not exceed a drop for the dose.

The above is the medicinal part of the treatment of diarrhœa; but this is only a part. The looseness is due to a catarrh; therefore with a child so affected every precaution must be taken that the mischief be not maintained or renewed by a series of fresh chills. The washing bath must be stopped for a few days, and only sponging of the face and hands, and of the buttocks after a stool, should be allowed. The feet and legs must be made and kept warm, and the abdomen, as the most vulnerable part, should be covered with a substantial flannel binder. In cold weather the child should be kept indoors, but his living rooms must be carefully ventilated, and no milk or food of any kind when not in actual use should be allowed to remain in them. Moreover, dirty napkins should be removed from the nursery at once.

For food, an infant may take cow's milk (boiled), lime-water, and barley-water in equal proportions; but it must be remembered that the barley-water must be fresh, and that in warm weather it is not a safe addition to the food when more than six hours old. Mellin's food may be added to each alternate meal for the sake of variety, and the child, if twelve months old, may take once a day a cup of veal broth with a rusk. If the looseness continues after two or three days of the treatment, it will be advisable to stop the milk and

give instead quite fresh whey and cream, broth, Mellin's food and barley-water or albumen-water, until the stools have again become natural.

In the case of older children, starchy puddings, jam, and fruit must be strictly forbidden, and the diet limited to rusk and milk, broth, sole or plaice boiled or broiled, dry toast and butter, etc. In them, too, the bath is to be forbidden for the time, and great attention must be paid to the warmth of the feet and legs.

Septic Diarrhœa, often called summer diarrhœa, is distinguished by two prominent symptoms: the temperature is raised, and the skin, especially that of the abdomen, is markedly inelastic. The latter is a sign of the utmost gravity, for, however mild the other symptoms may appear, unless the elasticity of the skin can be restored the child will surely die.

A high temperature is best reduced by enemas of cooled water; but in making use of the remedy we must bear in mind the tendency in this complaint to sudden collapse, and remember that a too rapid reduction of the bodily heat may be attended by serious symptoms of heart failure. It is wise to begin with a temperature of 80° to 85° F., and 4 oz. of boiled water cooled to this heat should be passed slowly into the bowel. Any sign of depression must be noted, and it is judicious to give a dose of brandy both before and after the operation, and apply heat to the child's feet when he is returned to his cot. The injection is to be repeated at intervals as the temperature rises again, gradually increasing the quantity of fluid, and using water as cool as the child will bear without showing symptoms of shock. We should try to keep the rectal temperature below 102°.

To restore the lost elasticity of the skin, the patient is wrapped as high as the arm-pits in a towel wrung out of cold water which has been made more stimulating by the addition of $\frac{1}{8}$ part of brandy or eau-de-Cologne, and is then closely covered from the neck downwards with dry blankets well tucked in. The child may remain thus swathed for many hours, or even several days, with great benefit. Every few hours he should be taken out of the wraps, rubbed dry, and repacked as before. The diuretic action of 10 drops of nitrous ether given in a little water every two hours is a useful addition to this treatment, for a copious flow of urine is often followed by immediate return of the healthy resilience of the skin. The wet pack is well borne as a rule, and usually helps to reduce the temperature of the body; but if it have an opposite effect, or lead to cardiac depression, its use must be at once abandoned. In that case, and indeed in all cases where the skin is definitely inelastic, especially if there be noted any tendency to general collapse, the hypodermic injection of a warm saline solution is a remedy of the utmost value. The solution is composed of 2 dr. of chloride of sodium and 4 gr. of chloride of calcium to the pint of distilled water. Of this half a pint is used on each occasion. The mode of proceeding is as follows: the fluid, heated to a temperature of 128°–30° F., is poured into a thermo-flask. A board perforated with a hole close to the edge is placed across the cot, and upon this the flask is inverted with its neck passing through the opening. The mouth of the bottle is closed by a cork, to which are fixed two Jacques rubber catheter tubes (No. 5), each about a foot long and ending in a fine trocar. The pointed ends are passed quickly through the loose skin of the abdomen or thigh, a few inches apart. At first the fluid is allowed to flow quickly into the subcutaneous tissue, but as it accumulates and forms a swelling under the skin, the force of the current is reduced by means of a clip fixed upon each tube. The time required for emptying the flask and passing the whole quantity of saline under the skin is from an hour and a half to two hours, and some hours usually pass before this is completely absorbed into the system. In bad cases the process is repeated twice a day—in the abdomen and thigh alternately. The immediate effect is to restore—at any rate temporarily—elasticity to the skin, and lessen the tendency to collapse. It is unusual to

find any sign of inflammation at the seat of injection: indeed, the procedure seems to be the cause of little inconvenience to the patient, and there is no doubt that it has been the means of saving many lives.

If vomiting be obstinate, the stomach should be washed out and nothing but cold sterilized water allowed to be taken. As the thirst is extreme, water may be given frequently; indeed, the child, if he can suck, may be allowed to take it at will from a feeding-bottle. After washing out the stomach, a poultice containing $\frac{1}{6}$ part of mustard should be applied to the epigastrium; and a few doses of calomel ($\frac{1}{6}$ gr. put upon the tongue every half-hour) help greatly to allay the irritability of the stomach. Ingluvin, too, is a remedy which often produces the happiest results, given in doses of 3 gr. every two or three hours.

As long as the vomiting continues, water should be the only fluid allowed to be taken, but when this is found to be retained, we may attempt cautiously to feed the patient with white wine whey, plain whey, or albumin water. These must be freshly made and be given cold in gradually increasing quantities, but at first we should allow only 1 teaspoonful every quarter of an hour. Milk is to be strictly forbidden.

To control the purging, astringents do more harm than good while the temperature continues high, and an antiseptic in some form is indispensable. The best of these, indeed the only one which I have found of any appreciable value, is calomel. It should be given in doses of $\frac{1}{6}$ gr. every two or three hours in conjunction with either powder of ipecac. and opium $\frac{1}{6}$ gr., or naphthalin $\frac{1}{2}$ gr., or resorcin 2 gr., or chloral hydrate 1 gr., or β -naphthol $\frac{1}{4}$ gr.

When the temperature has fallen, if the diarrhœa still continues, the astringent class of remedies may be resorted to. Of these perhaps the most useful is the salicylate of bismuth:—

R Bismuthi Carbonatis	gr v	Sodii Salicylatis	gr j
Glycerini	℥x	Aquæ	q.s. ad ℥j

Every three or four hours.

but any of the remedies recommended for catarrhal diarrhœa may be made use of.

One of the special dangers connected with septic diarrhœa is the tendency to general collapse, and the first sign of prostration must be met with energetic stimulation. The mustard and linseed poultice before recommended should be applied over the heart, or the infant may be put into a mustard bath and held there until the skin is well reddened; white wine whey in frequent doses of 1 teaspoonful should be given if it can be retained, and $\frac{3}{4}$ of a drop of liq. strychninæ, (1 per cent) with 5 drops of ether, should be injected under the skin. This latter remedy, with or without the ether, should be repeated every hour while the prostration continues. The hypodermic injection of the warm saline already referred to should never be omitted in these cases.

It sometimes happens that an attack of septic diarrhœa leaves behind it a general œdema without albuminuria. This is first noticed at a late stage of the complaint when the stools have nearly or even quite regained their normal appearance. In the many cases which have come under my notice, the cardiac physical signs have been normal, it has been exceptional to find any sign in the urine of infection by the bacillus coli or other organism, and there has been no special anæmia; often, indeed, the lips of the infant have been quite red. The œdema has been general, affecting the face as well as the limbs. Some of the cases I have treated successfully with adrenalin chloride—5 drops of the 1-1000 solution three times a day. In others the œdema has passed off quickly with—

R Caffeinæ Citratæ	gr $\frac{1}{4}$ -j	Glycerini	℥x
Tincturæ Digitalis	℥j-iv	Aquam	ad ℥iss
Spiritus Ætheris Nitrosi	℥xv		

M. ft. haustus. To be taken three times a day.

In children after the age of infancy the hypodermic injection of morphia has an almost immediate effect in checking the vomiting and purging. The earlier in the complaint the remedy is used the better ; it is of no further advantage after prostration has set in. For a child of four years of age $\frac{1}{20}$ gr. may be used, combined with 5 drops of ether, and the injection may be repeated in three hours if it is considered that a sufficient effect has not been produced.

Chronic Diarrhœa is the result of continually recurring catarrh of the bowel. To put a stop to it we have to take every possible precaution to avoid a fresh chill. The child's feet and legs, which are always bitterly cold, must be wrapped thickly in cotton-wool, and the washing bath—at any rate for the first fortnight—must be prohibited. When it is resumed the child must be sponged for one minute in hot (100° F.) soap-suds.

In the diet, milk must be forbidden, and the food should consist, for an infant, of fresh whey and barley-water ; whey and cream ; veal broth and barley-water ; and yolk of egg beaten up with veal broth or barley-water. Mellin's food or extract of malt may be added to any of these foods for the sake of variety.

Older children should take no milk, and very little starch. Pounded mutton or chicken, minced sole or plaice, egg, fat of bacon, toast or malted bread may be allowed ; butter may be given freely ; and well-boiled cauliflower or vegetable marrow, or, in winter, large Spanish onions stewed for five hours *with frequent changes of the water*, are unobjectionable. In bad cases, raw mutton pounded and strained through a sieve should be given in quantities as large as the child can be induced to take. This is especially useful when the patient is passing large unformed putty-like stools, consisting chiefly of fat and starch.

For medicine, nitrate of silver combined with opium should be our mainstay :—

R Argenti Nitratis Cryst.	gr $\frac{1}{8}$	Glycerini	$\mathfrak{M}x$
Tincturæ Opii	$\mathfrak{M}\frac{2}{3}$	Aquæ	q.s. ad \mathfrak{Jj}
Acidî Nitricî Diluti	$\mathfrak{M}\frac{2}{3}$		

The dose of the nitrate may be increased for older children to $\frac{1}{5}$ gr. This remedy is of inestimable value in all cases of prolonged gastro-intestinal derangement occurring, not only in children, but at every period of life. In the child it is often the only drug which appears to have any power of putting an end to the deranged state of the bowels. No fears need be entertained of pigmentation of the skin by the nitrate unless the remedy be continued for many months at a stretch. It may be given directly the acute stage has come to an end, and can be continued for six months together, if necessary, without interruption, and then stopped for a time ; and if it be returned to later, may be continued for another four months without risk. After ten months a further continuance of the treatment may possibly lead to a slight pigmentation of the skin of the face. These cases of chronic diarrhœa are so liable to relapse that a frequent return to medication by the drug is often found to be necessary. It must therefore be remembered that ten months' use of the remedy, whether the drug be given intermittently or in one continuous course, is the limit of certain safety as regards discoloration of the skin. In prescribing the nitrate it is advisable to warn the parents of the child that the medicine is one which cannot safely be used except under medical advice and supervision. This caution should never be neglected, for so obvious is the improvement set up by the use of the nitrate, that parents who have been impressed by the favourable results of the treatment will often in cases of relapse return to the remedy on their own initiative and without the knowledge of their medical attendant. This, it is needless to say, we must do our best to prevent. I have seen several cases in which permanent pigmentation of the skin has been induced by the incautious employment of the drug.

We may use as alternatives the salicylate of bismuth mixture recommended for septic diarrhœa, or any of the following :—

R	Liq. Hydrargyri Perchloridi 1-900	℥ x	Aquæ Chloroformi	
	Tincturæ Opii	℥ $\frac{3}{4}$	Aquæ Destillatæ	āā 3ss
			Three times a day.	

Or,

R	Extracti Hæmatoxyli	gr j	Glycerini	℥ x
	Tincturæ Krameriæ	℥ ii j	Aquæ	q.s. ad 3j
	Tincturæ Opii	℥ $\frac{3}{4}$		
			Three times a day.	

Or,

R	Salol	gr ij	Pulv. Cretæ Arom.c. Opio (B.P.)	gr ss
	Bismuthi Subnitratis	gr v		

Ft. pulv. To be given made into a paste with 2 or 3 min. of glycerin three times a day.

Any of the astringent mixtures recommended for simple diarrhœa may be used, but lead salts should be avoided as inadmissible for infants.

If the stools are large and pasty, a dose of powdered rhubarb 3 gr., aromatic chalk powder (B.P. 1885) 1 gr., should be given first, and after its action the nitrate of silver medicine; but indeed the latter is useful at any time after the acute stage has passed away, whatever be the character of the stools; taking care, however, that if an acute relapse occur with diarrhœa, the nitrate be discontinued until this has subsided. Much mucus in the stools is an indication for the perchloride of mercury mixture already recommended, or for the castor oil and opium mixture.

When the diarrhœa has been arrested, a tonic is often required to give tone to the bowel and brace up the mucous membrane. The best of these is perhaps pernitrates of iron (B.P. 1898), 2 drops of the solution being given with $\frac{1}{3}$ drop of the tincture of nux vomica in a teaspoonful of infusion of calumba, three times a day after food. It should be sweetened with glycerin.

In cases of tuberculous ulceration of the bowel with diarrhœa, the same measures will usually be sufficient to control the purging by curing the intestinal catarrh. The nitrate of silver is especially useful in these cases. It must be remembered, however, that the improvement in the stools does not imply an arrest in the ulcerative process.

Eustace Smith.

DIARRHŒA, TROPICAL.—Chronic diarrhœa, or recurrent attacks of diarrhœa, are very closely allied to dysentery. They frequently follow it, and are often associated with similar lesions. If mucus be present in such stools, with or without blood, the disease should be regarded and treated as chronic dysentery. If amœbæ are found, the diagnosis is certain. In some cases flagellates such as *Lambliæ intestinale* or their cysts are found. In these cases intestinal antiseptics, such as β -naphthol 5 to 10 gr., as tabloids, given every four or six hours, are often markedly beneficial. In others, a close enquiry into the habits and diet may reveal irregularities as the cause; the commonest errors are abuse of alcohol and an excessive meat diet.

In many such cases an increase in the amount of fresh vegetable food, not excluding green vegetables, making free use of native roots, such as yams, arrowroot, sweet potatoes, etc., and limiting the amount of meat, will result in speedy improvement. Moderate but regular exercise is of great value. A preliminary purgative should be given before commencing the treatment.

In other cases the diarrhœa is due to incomplete evacuation of the intestinal contents and subsequent irritation from decomposition of the portion of excreta retained. In such cases the regular administration of rectified petroleum, or chrisamol in nightly doses of 1 dr. to $\frac{1}{2}$ oz., is often beneficial.

The abdomen and loins must be kept well covered by a broad flannel belt or bandage. (See also DIARRHŒA, HILL.)

C. W. Daniels.

DIATHERMY.—(See THERMOTHERAPY.)

DILATATION OF STOMACH.—(See STOMACH, DILATATION OF.)

DIPHThERIA.—The two cardinal points in the treatment of this disease are : (1) *The early use of antitoxic serum ; and* (2) *Rest in bed.*

1. The imperative need of giving antitoxic serum (or antitoxin, as it is briefly called) at the earliest opportunity, in all forms of diphtheria, cannot be too earnestly impressed upon the practitioner, even though the nature of the disease may be doubtful when the patient is first seen. Diphtheria is usually subtle in its onset, and frequently swift in its evolution. In its treatment hours are of value, and the earliest hours are the most precious. It is perilous to wait till diphtheria bacilli have been demonstrated (unless they are demonstrated on the spot in a smear preparation), till the local exudation has become definitely membranous, or till symptoms of toxæmia appear. In the large majority of cases, antitoxin, if given on the first day, will cut short the disease by preventing the spread of the membrane, and by neutralizing the action of any toxin that may, even so early, have been absorbed. Paralysis and cardiac troubles are rare and slight in cases treated with antitoxin on the first day.

When there is a reasonable suspicion of diphtheria of whatsoever form (i.e., faucial, laryngeal, etc.), 2000 units of antitoxin should be injected. In mild cases seen on the first day, this dose will usually suffice ; but if the case is a severe one, as it often is after two or three days' illness, the dose must be increased to 8000, 10,000, or even 20,000 units. As that portion of the serum which contains the antitoxin is not absorbed quickly, it is advisable to give the requisite amount in a single dose. If membrane still persists in large amount on the third day after the injection, half the first dose may be then injected. The writer is of opinion that 16,000 to 20,000 units, altogether, is about the limit beyond which it is unnecessary to go ; but no harm can be done to the patient by giving larger doses if they are thought to be desirable.

The most efficacious mode of administering antitoxic serum is by intravenous injection. There are, however, several practical objections to this, and the most convenient method is by hypodermic injection.* The best site is the lateral region of the abdomen. If given anywhere in the back, the patient may be prevented for three or four days, by the tenderness and stiffness that sometimes follow, from lying on the back with comfort. The swelling caused by the injection of the serum usually disappears in fifteen to thirty minutes, according to the amount. Care should be taken that the serum enters the subcutaneous tissue, and not the skin, as injection into this structure is very painful. Injection into muscle is also more painful than into the subcutaneous tissue, but absorption takes place more quickly. Every aseptic precaution should be used ; the skin should be washed with soap and water, and painted with iodine, and the syringe boiled just before the injection. The most convenient forms of syringe are Roux's and those made (except as regards the needle) entirely of glass. The needle should be connected with the nozzle by three or four inches of indiarubber tubing.

* Experimental evidence shows that intravenous injection is more efficacious than subcutaneous. The whole of the antibody (antitoxin) in the serum is at once introduced into the circulation, whereas in subcutaneous injection it takes from two to three days for the antibody to be present in the circulation in any efficacious amount ; and even then the amount present is very much less than the amount injected. The practical difficulty is that it is by no means always an easy matter, in a severe toxic case of diphtheria, to hit off a vein in which to inject the serum. As for the administration by the mouth or rectum, experimental evidence is quite against its efficacy. For the best method of performing intravenous injection, see the article on SPECIFIC THERAPY.

Before injecting the serum, any air that is present should be expelled from the needle, tubing, and syringe. The puncture made by the needle should be sealed with a little cotton-wool dipped in collodion. When filling the syringe, be careful that the serum is exposed to the air for the shortest possible time. Once having uncorked a bottle or tube of serum, use all the contents immediately; do not recork the bottle to keep for future use. But so long as a bottle has not been uncorked, and has been preserved in a dark, cool place, the serum retains its efficacy for several months. J. F. Anderson has found by experiment that antitoxic serum kept at ordinary room temperature loses 20 per cent of its potentiality in a year. If kept at 5° C. it loses 5 per cent a year. Dried serum kept in the dark at 5° C. remains unimpaired for at least five and a half years.

Antitoxin will sometimes give rise to a rash (urticaria or a variety of hyperæmic erythema) which itches intolerably; the application of spirit lotion, or lead and opium lotion, or menthol ointment (1 dr. of menthol to an ounce of par. alb. mol.) will allay this irritation; calcium lactate in 5-gr. to 15-gr. doses should also be given every four hours. For the pains in the joints and fasciæ that sometimes occur, lead and opium lotion, or glycerin and belladonna, externally, with a suitable dose of laudanum internally, is the best treatment. Sodium salicylate is not usually of much avail. An abscess at the seat of injection will occasionally occur.†

2. Next to antitoxin, *rest* is the most important factor in the treatment of diphtheria. The pathological change most to be feared is fatty degeneration of the cardiac muscle. It is highly probable that this occurs in all cases where toxæmic symptoms, however slight, are present. It certainly occurs in all severe cases; and it sets in early in the disease. Therefore the patient should be confined to bed at once, and kept there for ten days or a fortnight after the disappearance of the exudation in mild, or of toxæmia and cardiac symptoms in severe, cases; indeed he must be restricted to the recumbent position, and the effect of sitting up in bed should be observed for a few days before he is allowed out of bed. The condition of the circulation should be carefully and frequently observed. When the patient is first allowed out of bed, it should only be to sit in an easy chair for two or three hours; and the effect of even this slight exertion should be carefully watched. Any sudden or prolonged exertion is to be prohibited absolutely for several weeks after an attack of diphtheria. the length of time varying according to the nature of the attack. If the exudation has persisted for several days; if there has been albuminuria for more than one or two days; if there has been any cardiac irregularity, or any paralysis (nasal voice, squint, etc.), the necessity of this prohibition is emphasized. In severe cases, not only physical but mental excitement is to be avoided.

So long as any exudation is present, local treatment should be carried out with a view to removing it; but if the patient vehemently resists, as is often the case with children, it should be omitted, because the struggles of the patient are harmful to him. When the exudation is extensive, syringing the nose and fauces should be practised; but with limited exudation, gargling or swabbing will be sufficient. The following liquids are useful: warm water, normal salt solution,

† The rashes, etc., due to serum usually appear a week to a fortnight or more after the injection. But occasionally when a patient has already had horse-serum several weeks or months before, the rash may come out within a few hours or a day or two; and there may also occur severe symptoms—high temperature, rigor, collapse, cyanosis—in addition (anaphylaxis, supersensitization). Hence some caution should be exercised in horse-serum for relapses or second attacks; it should be given only when they threaten to be serious. There is also evidence to show that these symptoms in their most severe form are prone to occur, even when the serum is given for the first time, in persons who are the subjects of asthma, or who exhibit symptoms resembling “hay fever” immediately after having been in the close vicinity of horses. More than one fatal case has occurred.

saturated solution of boracic acid, chinosol 1-600 to 1-1000, and the following alkaline solution :—

R Sodii Biboratis	$\overline{3j}$	Sodii Chloridi	$\overline{3ss}$
Sodii Bicarbonatis	$\overline{3j}$	Tincturæ Lavandulæ Compositæ	$\overline{3j}$
Potassii Chloratis	$\overline{3ss}$	Aquæ	q.s. ad \overline{Oj}

Solutions that are so strongly bactericidal as to be able to destroy the bacilli *in situ* do more harm than good, being as inimical to the mucous membrane as to the micro-organisms. By setting up inflammation they actually further the spread of the diphtheritic exudation.

Syringing should be performed with a ball syringe, or, better still, with a douche-can and tube. When using these appliances, care should be taken that the nozzle is not so long as to reach the soft palate, lest injury be inflicted on this structure.

In nasal diphtheria, the nasal fossa should be syringed out with the alkaline solution mentioned above. Hæmorrhage is very rarely so profuse as to require treatment. If it occur, the nose should be syringed with iced water, having alum or tannic acid dissolved in it. In very severe cases of hæmorrhage the nares must be plugged.

Cardiac Failure.—In diphtheria this occurs in two forms : (1) There is the comparatively slowly progressing failure, which may be observed to a greater or less degree in all cases of toxæmia during the first fortnight of the disease. The ordinary cardiac stimulants are quite useless in this condition. Adrenalin chloride is recommended by Dr. J. D. Rolleston ; but the present writer is bound to say that the drug has not come up to his expectations : 5 min. of the solution in a drachm of camphor water should be given every four hours, the dose being gradually increased to twice these amounts every two hours. If there is vomiting, and rectal feeding has to be resorted to, 3 dr. of the solution (15 min. of adrenalin) may be given in each nutrient enema every four hours. (2) There is the cardiac paralysis of convalescence. This frequently takes the form of a syncopal attack. Here strychnine, brandy, and similar stimulants are of great value. The patient should be placed on his back with his head lowered, and hot-water bottles should be applied to the feet. But if the warnings already given as to the necessity of strict rest during the first few weeks of convalescence are heeded, serious attacks of syncope will not often be met with.

Vomiting is another symptom of diphtheria that frequently calls for treatment. This, too, may be early or late, and the former is most intractable. The following treatment, introduced by Dr. G. C. Garratt, should be tried : All nourishment by the mouth must be omitted, and nutrient enemata given every four hours, 20 to 30 min. of tincture of belladonna being added to each enema, with 20 gr. of potassium bromide once every twelve hours. About an hour after each dose of bromide, introduce slowly into the child's stomach 10 or 12 oz. of water at 115° F., to which a little sodium bicarbonate has been added. In order that this may be done, the child must be wrapped in a large towel ; the body and legs are held by a nurse, and the head is laid upon a mackintosh spread over the operator's knees. A good-sized silk-gum œsophageal tube, previously bent to a suitable curve, must be passed through the mouth into the stomach. If the water is rejected, pour in some more till it is retained. Take out the tube quickly, and after waiting a few minutes, put the child to bed. Strychnine and alcohol must not be given. Vomiting occurring at a later stage is best treated by giving nourishment by enemata.

Paralysis.—If paralysis, however slight, sets in after the patient has been allowed to get up, he should be ordered back to bed at once. The length of time it will be necessary to keep him there depends upon the course and extent of the paralysis.

If there is regurgitation of fluids through the nose, or coughing and spluttering when the patient drinks, he should be allowed only thickened liquid food, such as cornflour. Young children should be fed by means of a tube passed through the nose and œsophagus; if there is vomiting, nutriment must be given by means of enemata till it ceases; and if enemata are not retained, subcutaneous injections of sterilized horse-serum, 20 to 30 c.c. every four hours, may be given for two or three days.

When the respiratory muscles are affected, the foot of the bed should be considerably raised, to prevent saliva trickling into the air-passages, and to facilitate the escape of mucus from the lungs; 20 to 30 min. of tincture of belladonna should be given by the mouth or rectum every four hours. The patient may also be made to inhale oxygen at intervals. Ciliary paralysis will prevent an adult from reading; the provision of suitable plus glasses will remedy this inconvenience. Strychnine is a very useful drug in paralytic cases. When the patient is beginning to recover, the wasted muscles should be massaged.

Laryngeal Diphtheria.—Directly there are signs of affection of the larynx, the patient should be placed in a warm moist atmosphere. This may be accomplished by means of a bronchitis kettle. If the patient is in a ward or a large room, it will be necessary to put him under a tent into which the steam escapes. Another dose of antitoxin should be given. Under this treatment most cases will get well without the surgeon's aid. But if the laryngeal symptoms are urgent, surgical relief must be afforded. The writer usually waits till the dyspnœa prevents the patient getting any rest, or till there is considerable recession. In private practice the relief afforded must be by tracheotomy, but in hospital practice it should be by intubation. The latter operation requires the constant attendance of a medical man within three or four minutes' call; hence it is unsuitable for private practice.

In hospital practice the only contra-indication to intubation is a moribund state of the patient from suffocation; then tracheotomy is essential.

Intubation.—The instruments necessary for intubation (*Fig. 14*) are: (1) The intubation tube; (2) The obturator or pilot, which fits into the lumen of the tube, and is rigidly fixed by a slot and bolt to (3) The introducer; to the introducer is attached a sort of arm, which can be moved by the thumb in such a way as to release the tube from the pilot; (4) A gag. A long loop of silk or thread is attached to a hole in the head of the tube.

The instruments figured are those modified by Bayeux from O'Dwyer's pattern, and made by Collin, of Paris. A set of all the requisite instruments is supplied in a box; besides the instruments mentioned, there is an extractor for the removal of the tube. The size of the tube to be used varies with the age of the patient. An anæsthetic is quite unnecessary. The patient should be laid flat on his back. In most cases of diphtheria it is undesirable to place the patient in the upright position on account of the liability to syncope. It is, moreover, easier to steady the head in the recumbent than in the upright posture. The operator requires the freest control over the instrument at the moment when the tube is being introduced into the larynx, and he will obtain it by placing the recumbent patient well below him. The writer lays the patient across the end of the bed, so that the patient's right side is nearest to its foot. The operator stands at the foot of the bed. One nurse holds the patient's head, another secures the arms and legs. An intelligent child will often not require to be held, so far as the arms and legs are concerned. The operator should satisfy himself that the tube is not too tightly fixed on the pilot, and that it can be easily pushed off by the arm on the introducer. The pilot should be smeared with a little vaseline or olive oil. The tube should be placed upon the pilot

Fig. 14.—INTUBATION INSTRUMENTS.

- (A) Intubation Tube.
 (B) Obturator or Pilot; at (a) there is a joint to enable it to fit easily in the tube.
 (C) Introducer; the notched upper portion (b) of the pilot is inserted into a socket (c) at the end of the introducer, and is kept firmly in place by the bolt (d); (e) is the movable arm of the introducer for pushing the tube off the pilot. In the illustration it is much more depressed than it would be at the moment of use. The illustrations show the instruments separately, and put together for use. The tube (A), where shown separately, is seen from the front.
 (D) Gag.
 (E) Extractor; the blades are slightly separated.

so that the projecting portion of the head is directed backwards as regards the patient. The gag is inserted into the left side of the mouth, and is kept in place by the nurse who has hold of the head, which must be kept straight, with the face looking directly upwards. If there is much mucus in the mouth and pharynx, it should be removed with a swab. The operator, holding the introducer, with the pilot and tube (with thread) fitted into place, in his right hand, introduces his left forefinger behind the tongue to the epiglottis, the condition of which is noted.* Not infrequently it is bent backwards, and must be straightened before the tube can be introduced into the larynx. The finger is then pushed over, or by, the epiglottis, and the arytenoid cartilages and the orifice of the larynx are felt. Here, again, the operator notes the condition of the parts, and acts accordingly. Extreme swelling of the glottis, for instance, would induce him to put a smaller tube on the pilot. The tip of the finger is held against the arytenoids just over and at the back of the laryngeal orifice. The end of the pilot is then passed carefully along the anterior surface of the curved forefinger till it reaches its tip. By this movement the end of the instrument is brought over the laryngeal orifice. Before inserting the tube in the larynx the operator must be certain that the whole tube—not only its lower end—is in the middle line, for usually this is not the case while it is being passed along the finger. Having rectified the position of the tube, the operator slips it past the tip of his finger into the larynx. In performing this action I find it nearly always necessary to flex slightly the right wrist and at the same time to raise the right elbow. I say ‘slips into,’ for undue pressure must be avoided. When intubation is performed with the patient in the upright position, the tube will often enter by the weight of the instrument, without any pushing. If laryngeal spasm prevents the entry of the tube, it may be overcome by very gentle but continuous pressure; or advantage may be taken of an inspiration to slip the tube past the cords.

The tube is then partly released from the pilot by means of the arm of the introducer, and the pilot is withdrawn. During this action, the tip of the left forefinger must on no account be removed from the head of the tube, which will be resting on the arytenoid cartilages; otherwise the tube is almost certain to be pulled out of the larynx. In some cases it will be found, while withdrawing the pilot, that the tube has not completely entered the larynx; but the slight pressure exercised by the finger on the head of the tube during the withdrawal of the pilot sends the tube home.

When the introducer and pilot have been removed, the operator, by means of the tip of his left forefinger, ascertains that the tube is safely in the larynx. The loop of thread should then be removed by cutting and pulling it gently through the hole in the tube, taking care that the knot in the thread is not pulled against the small hole in the tube. While the thread is being removed, the finger should be kept on the head of the tube, or the latter will certainly be pulled out of the larynx. The gag is taken out, and the patient, if relieved, is put back to bed.

Some operators leave the thread attached to the tube, in which case it must be fastened round the patient's left ear or, with a piece of plaster, to his cheek. The writer prefers to dispense with the thread; it irritates the epiglottis, tongue, and angle of the mouth; the child will pull it and remove the tube; hence it is necessary to restrain his hands by cardboard splints on the arms, or by some other method; and this irritation and restraint are most irksome.

* It is convenient to twist the silk or thread loop once round the right index finger, keeping it moderately tight. It will help to secure a loosely fitting tube in place on the pilot. When the tube is in the larynx, it is easy to disengage the thread from the finger.

The only reason for retaining the thread is that the nurse may be able to pull out the tube at once, should it become suddenly blocked. But as a matter of fact this seldom happens; moreover, the nurse can be taught to get the tube out by the method of expression, to be described below.

Since this account of intubation was written certain improvements have been made in the instruments. It happens occasionally that during the withdrawal of the obturator, or pilot, the bolt slips, and the pilot is left in the tube. To obviate this accident, the pilot, in instruments of the pattern described above, is now made to fix by a long curved rod to the introducer at a point near the handle. But a much more important improvement is that which has been made in the shape and size of the pilot. Not infrequently, even in the most practised hands, there is considerable difficulty in disengaging the pilot from the tube. Again, frequent use and cleaning weaken the joint which is in the middle of the pilot; and instances have occurred in which the joint has broken during the operation, and its lower portion has remained in the tube or been swallowed by the patient. It cannot slip through the lower end of the tube into the trachea, because the bulb at its end is larger than the lower orifice of the tube. In Moreau's instrument the pilot is jointless and very short; it is fixed to the introducer by a bolt, as in the instrument described above. When the pilot is in position, the tube is prevented from slipping off it by means of a catch which fits under the projecting posterior part of the top of the tube. This catch is at the end of a long movable arm, which, bent and pivoted at the angle of the introducer (similar to that shown in *Fig. 14*), is continued to near the handle of the latter, where it is manipulated by the operator. This arm replaces in function that marked (*e*) in *Fig. 14*, and by it the pilot is released with the greatest ease. The pilot and introducer are hollow; when they are put together there is a continuous open passage from the tube, through the pilot and introducer, right up to the end of the handle of the latter. At this spot is placed a whistle. Directly the tube enters the orifice of the larynx, every expiration made by the patient blows the whistle, and the operator is made aware that the tube is entering the right orifice.

To meet the difficulties of the hinged pilot which have been mentioned, Avirignet's instrument has also been invented. It is an extremely simple one. The pilot consists of a steel spring which is fastened permanently to the introducer, and terminates below in a bulb. But the spring is too delicate to stand much wear, and should it break while in the tube when the latter was in the larynx, the portion broken off would slip into the trachea; for in the specimens of the instrument seen by the writer, the lower orifice of the tube is not narrow enough to prevent this accident.

The writer is of the opinion that Moreau's ingenious instrument is the best at present in the market. It can be obtained from Collin, of Paris. The method of introducing the tube is the same as that described for the instrument shown in *Fig. 14*.

Extubation.—Removal of the tube may be accomplished in two ways. The first is by expression ("*énucléation*"). This is most easily performed with the patient in the sitting position—an objection to this method in toxic diphtheria—but it can also be done while the patient is lying on his side. The patient's head is thrown back as far as it will go. This position throws the larynx and trachea prominently forward. The patient's mouth should be open. The operator places the right thumb on the trachea immediately below the larynx, and his left hand on the occiput. Then with simultaneous and sudden actions he presses his thumb firmly backwards towards the spine and flexes the patient's head. The lower portion of the tube has the shape of an inverted, truncated cone, and under the pressure of the thumb the tube slips up into the pharynx,

against the posterior wall of which it impinges; by the forward movement of the pharyngeal wall in the flexion of the head the tube is directed into the mouth, and even out of it if it is open. Removal may also be effected by the extractor, the two small, separating blades of which must be inserted into the upper part of the tube. The patient must be gagged, and the method of putting the blades into the tube is very much the same as that employed in introducing the tube into the larynx.

In cases where there is laryngeal spasm immediately after the first removal of the tube, so that immediate re-intubation is required, a small dose of opium, or bromide of potassium, or chloral hydrate, should be given a few hours before it is proposed to remove the tube again.

The patient who is wearing an intubation tube must be fed by means of an œsophageal catheter passed through the nose. But he may have a sip of water occasionally, for the slight cough thereby excited helps to keep the tube clear. After three or four days the tube should be removed. It may have to be returned. The writer is of the opinion that if the patient cannot do without the tube after three periods of retention of three or four days each, recourse should be had to tracheotomy. If the tube is frequently expelled by coughing, tracheotomy should be performed.

Intubation should never be undertaken without having the tracheotomy instruments ready to hand, because, very occasionally, diphtheritic membrane may be pushed down during intubation so as to block completely the lumen of the trachea, in which case the patient rapidly becomes worse, and tracheotomy must be performed. This operation will be necessary also in cases where repeated intubation has failed to relieve. (See LARYNGEAL OBSTRUCTION.)

Vulvar and conjunctival diphtheria should be treated locally by frequent irrigation with a saturated solution of boracic acid, and warm boracic fomentations.

No patient convalescent from diphtheria should be considered to be free from infection till at least three weeks have elapsed since the local exudation has finally disappeared, and the parts which have been affected have regained their normal appearance.

Quarantine Period.—One week; during this period all persons who have come in contact with the patient (contacts) should be examined daily for clinical evidence of diphtheria.

In institutions for children, when prompt removal of two or three successive cases has failed to arrest the outbreak, the prophylactic injection of antitoxic serum is of value. All the children who have been exposed to infection should receive 500 to 600 units subcutaneously.* Lately, Behring has introduced a prophylactic which is said to have been very efficacious in a few cases in which it has been tried. It consists of a mixture of very powerful diphtheria toxin and antitoxin in such proportions that tests on guinea-pigs show that it contains only a slight excess of toxin. It is given subcutaneously in small amount ($\frac{1}{16}$ c.c.). But the occasions for prophylactic measures of this description are, in this country, few and far between. (See also SPECIFIC THERAPY, LARYNGEAL OBSTRUCTION, LARYNGITIS, and FEVERS, ACUTE INFECTION.)

E. W. Goodall.

DIPLEGIA.—(See PALSIES, CEREBRAL.)

DIPSOMANIA.—(See ALCOHOLISM.)

* But prophylactic injections should not be given without strong reasons; for should serum have to be given at any subsequent date the phenomena of supersensitisation may be produced (see note on p. 250). It is not advisable to give a prophylactic injection to any person who is subject to asthma.

DISLOCATIONS.

Lower Jaw.—This dislocation is always in a forward direction, and is more commonly bilateral. In recent cases there is usually little difficulty in reduction, the patient often effecting this without assistance.

REDUCTION.—No anæsthetic is required as a rule. (1) The patient is seated in a chair, and the surgeon stands facing him. The thumbs, well guarded by wrapping in handkerchiefs, are introduced into the mouth and placed far back on the lower molar teeth of each side (*Fig. 15*). The thumbs then press the back part of the jaw downwards, whilst the fingers of the two hands, meeting beneath the chin, press the fore part of the jaw upwards. The condyles are thus levered downwards, and when once disengaged from the eminentia articularis slip into their socket, and the jaw closes with a snap. (2) When the first method fails, wedges of cork are placed between the molar teeth of the upper and lower jaw, as far back as possible. The surgeon then presses the chin firmly upwards, and thus levers the condyle downwards, reduction taking place as before. If the dislocation be unilateral, the measures detailed are applied to the affected side only.

After-treatment.—A four-tailed bandage is put on as for a fracture of the jaw, the patient being fed on slops. At the end of a week careful passive movements are begun. The dislocation is apt to recur and the joint to become permanently lax; it is therefore advisable to keep the bandage applied for a fortnight longer, removing it thrice daily for the purpose of movements; moreover, the patient should be instructed to avoid for three months opening the mouth widely.

Sternal End of the Clavicle.—Dislocation forwards is by far the most common displacement. Backward and upward dislocations also occur, the order of frequency being as named.

Forward Dislocation.—The sternal end of the bone is more or less completely displaced on to the front of the manubrium sterni.

REDUCTION is readily effected, and no anæsthetic is required. The surgeon stands behind the patient, and placing his knee between the scapulæ, pulls the two shoulders backwards. Direct pressure on the displaced end of the clavicle may be applied at the same time.

After-treatment.—A large pad is placed in the axilla, and the arm is bandaged to the side, the elbow being kept well forwards. It is very difficult to maintain complete reduction, but the parts should be kept at rest in the manner described for three weeks, in order to allow of union of the lacerated ligaments. It is well to warn the patient of the probability of permanent deformity, but at the same time he may be assured that there will be little or no impairment of the utility of the limb.

Backward and Upward Dislocations are of rare occurrence. They are reduced and treated as in the forward variety, and the above remarks with regard to permanent deformity and utility hold good. In backward dislocations, dyspnoea and dysphagia may be produced by the pressure of the displaced end of the clavicle, and the great vessels may be similarly pressed upon. If the pressure cannot be relieved, owing to the failure of reduction, the head of the bone must be excised.

Acromioclavicular Joints.—The ligaments being torn, the scapula, with the whole upper limb, drops downwards, and leaves the acromial end of the clavicle projecting beneath the skin over the shoulder. Occasionally the clavicle passes beneath the acromion instead of, as in the first case, resting upon its upper surface.

Fig. 15.—Reduction of Dislocation of Lower Jaw.

REDUCTION is readily effected by pulling the shoulder backwards and applying direct pressure in a downward direction to the displaced end of the clavicle.

After-treatment is unsatisfactory. In many cases it is well-nigh impossible to keep the bones in position. The most likely method of effecting this is to place a soft pad over the outer third of the clavicle and to apply a plaster-of-Paris spica bandage to the shoulder, afterwards keeping the patient in bed for three weeks. The danger of injury to the skin from pressure over the displaced acromial end of the clavicle must not be lost sight of. If pain or serious impairment of movement results from persistence of the deformity, the cartilage is removed from the contiguous bony surfaces in the joint, and these are then wired together.

Shoulder.—At least 50 per cent of all dislocations take place at the shoulder-joint. It is, however, unusual to meet with a case of dislocation of the shoulder in a patient under the age of twenty. Violence, such as would in the adult produce this injury, is in early life more likely to give rise to a fracture of the clavicle or a dislocation at the elbow.

The classification is as follows :—(1) Downwards—subglenoid ; (2) Forwards—subcoracoid, subclavicular ; (3) Backwards—subspinous ; (4) Upwards—subacromial, supra-acromial. The head of the humerus leaves the joint through the lower and anterior part of the capsule, and thus comes to lie beneath the glenoid

Fig. 16.—Reduction of Dislocation of Shoulder by Kocher's method. A.—The arm is pressed to the side and externally rotated. B.—The arm being maintained in an externally rotated position, the elbow is raised in front of the body. C.—Reduction completed by internally rotating the arm.

cavity. The head may remain here, giving rise to a *subglenoid* dislocation ; more commonly, passing forwards, it reaches a position in front of the glenoid fossa and below the coracoid process, constituting a *subcoracoid* dislocation. Very rarely the head passes still further forwards and inwards, and rests beneath the clavicle, a *subclavicular* dislocation being thus produced. Instead of taking this forward course, the head of the humerus may, after reaching the subglenoid region, pass backwards into the subspinous fossa, and thus give rise to a *subspinous* dislocation—a condition even more rare than the last described. Such unusual forms as the *subacromial* and *supra-acromial* dislocations need no further mention.

REDUCTION must be undertaken at once. Should there be doubt in diagnosis, the x-ray screen may be employed if available ; it is useless and dangerous to wait for twenty-four hours in the hope that the swelling may diminish and facilitate examination. During that time the displaced head of the bone may cause irreparable damage to the nerves of the brachial plexus or the axillary vessels. Whenever possible a general anæsthetic should be administered. The necessary manipulations are thus rendered easier, less force is required, and less damage is likely to be caused to the structures around the joint.

For *Subcoracoid* and *Subglenoid* Dislocations the following methods are

applicable, and should be applied in the order stated. (1) *Traction downwards and outwards.* The patient is placed flat on his back on a couch. The surgeon stands beside him, and, grasping the arm above the elbow, pulls steadily upon it in a downward and outward direction. Then, abducting the limb, he gradually changes the direction of the pull until the arm is at right angles to the body. An assistant standing on the other side of the patient keeps the trunk steady by means of a towel which is passed around the chest, and upon which he pulls in a contrary direction to the traction exercised by the surgeon. This method is effectual in the great majority of cases, especially if an anæsthetic be given. (2) *Kocher's method.* The patient, if not anæsthetized, sits upright in a chair, and a towel, which is passed round his chest and the back of the chair, is held by an assistant, who thus keeps the trunk in a steady position. If anæsthetized, the patient lies on his back, and the assistant steadies the trunk by pressing each shoulder firmly down upon the couch, applying his hands over the front of the acromion and clavicle. The surgeon stands on the affected side of the patient, and flexing the forearm to a right angle (*Fig. 16*), grasps the limb with one hand just above the elbow and with the other the wrist. He then presses the elbow

Fig. 17.—Reduction of Dislocation of Shoulder by the "Heel in Axilla" method.

firmly to the side of the chest, and, maintaining it thus, moves the wrist outwards until the forearm points directly outwards from the side of the body. The arm being kept in this externally rotated position, he next elevates the elbow in front of the body until it lies almost on a level with the shoulder, and finally internally rotates the forearm by swinging the wrist across so that the hand comes to rest on the opposite shoulder. (3) *Extension with the heel in the axilla.* The patient lying flat on his back, the surgeon sits on the edge of the couch and places his unbooted heel in the axilla. Seizing the wrist, he pulls upon it in a downward and outward direction, and then bringing it towards the side he levers the head of the humerus outwards, his heel acting as a fulcrum (*Fig. 17*). Care must be taken that the skin of the axilla is not wrinkled into folds, but that it lies flat and smooth under the heel.

For Subspinous and Subclavicular Dislocations.—Extension, aided by rotary movements, is made in the axis of the dislocated humerus until the head of the bone is brought beneath the glenoid fossa. After this, the methods already described will complete the reduction.

After-treatment.—A wool pad is placed in the axilla, the arm is bandaged to the side, and the forearm supported by a sling. At the end of a week massage is begun, and passive movements are carried out daily with gradually increasing freedom. Particular care should be taken to obtain free abduction, but the combined movement of abduction and external rotation is at first to be avoided. At the end of a fortnight the bandage is discarded for a sling. At the end of three weeks active movements are encouraged, and the patient may return to work at the end of five or six weeks.

Unreduced Dislocations.—If more than six weeks have elapsed since the dislocation, great difficulty will be experienced in reduction; and having regard to the danger of fracture of the humerus, rupture of the axillary vessels, or laceration of the branches of the brachial plexus, it may be looked upon as unjustifiable to attempt the reduction by ordinary methods of a dislocation of more than two months' standing. In cases, therefore, where a trial under an anæsthetic of the methods given above fails to effect reduction, or in cases in which such attempts are thought inadmissible, the question of operation has to be considered. The utility of the limb in its dislocated position, the general condition and occupation of the patient, and the amount of pain and discomfort suffered, will decide for or against operative measures. The best results are given by an excision of the head of the humerus, which relieves the pain and restores the mobility of the limb.

Habitual Dislocations.—Occasionally, after a dislocation has been reduced, it is found to recur at the result of very slight violence. Without any warning, whilst the patient is perhaps merely raising the arm, the shoulder becomes dislocated. In these cases the recurrent displacements tend with time to become more and more frequent, and give rise to such serious disability that operative measures are needed. The best results are given by removing a strip from the front of the capsule of the joint and suturing the gap thus made. Before operation a skiagram should be taken, as in some cases it may be a fracture of the glenoid fossa which is responsible for the condition.

Fig. 18.—Reduction of Dislocation of Elbow.

Elbow.—This injury is of frequent occurrence, especially in early life, since the cartilaginous coronoid process—the main factor in preventing backward displacement—is then of small size. The injury is almost always a backward displacement of the ulna and radius from the lower end of the humerus, the two bones of the forearm maintaining their relative positions to each other. Lateral and forward displacements also occur, and occasionally the ulna alone is dislocated backwards, the relationship of the radius and humerus being unchanged. Dislocations of the radius are considered separately.

REDUCTION.—An anæsthetic is usually unnecessary. The “knee” method is applicable to all the above-mentioned dislocations except that in the forward direction. The patient sits in a chair, and the surgeon, resting his foot on the chair, places his knee against the front of the lower end of the humerus. Holding that bone steady with one hand, he flexes the patient's forearm with the other, which seizes the limb at the wrist (*Fig. 18*). The lateral aspect of the surgeon's knee acts as a fulcrum, and the flexion of the forearm levers the upper end of the ulna away from the humerus until the coronoid process

is disengaged, when the bones slip into position. The forward dislocation may be reduced by pushing the forearm firmly backwards whilst keeping it fully flexed.

After-treatment.—The arm should be kept in a sling, and active movements forbidden for two or three weeks. Passive movements and massage may be undertaken at once.

Unreduced Dislocations.—If a dislocation has remained unreduced for a period of more than a month, replacement is unlikely, and is accompanied by considerable risk. Up to the time mentioned the method above described may be employed under an anæsthetic, preceded by movements to break down adhesions. If these fail, or if lapse of time has rendered the attempt inadmissible, operation should be resorted to—if the general condition of the patient is favourable and a movable elbow of importance. The operation called for is an excision of the elbow, and it gives satisfactory results.

The Upper End of the Radius.—As a result of falls on the hand, dislocations of the upper end of the radius may take place in a forward or backward direction.

REDUCTION is readily accomplished without an anæsthetic by flexing the forearm to a right angle, and pulling upon it in that position whilst the thumb of the other hand makes direct pressure in the requisite direction upon the displaced radial head.

After-treatment.—Some care is called for to prevent the recurrence of the displacement. The elbow is kept fully flexed upon a poroplastic splint for three weeks. After a few days, however, the splint may be removed daily for the purpose of careful massage and passive movements in the direction both of extension and rotation.

Dislocation of the Radius Downwards.—“Pulled-elbow” results from the practice of dragging children along by the hand. The radial head is separated from the capitellum of the humerus, and a portion of the orbicular ligament slips in and becomes nipped between the articular surfaces. The child cries with the pain and keeps the elbow semi-flexed, whilst tenderness and swelling are noted on examining the joint from behind.

REDUCTION.—Fully flex the limb, and, after keeping it in that position for a few moments, rapidly extend it. No after-treatment is needed beyond controlling the movements of the joint for a day or two.

Wrist.—This injury is of rare occurrence. The carpus passes backwards from the radius.

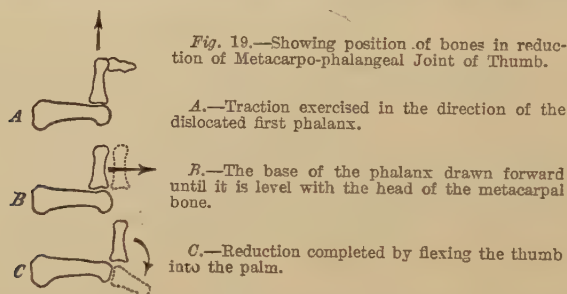

REDUCTION is readily effected by pulling upon the hand.

After-treatment.—The forearm and hand are placed upon a well-padded straight splint, and are lightly bandaged to it. The splint must not reach beyond the metacarpo-phalangeal joint, and the fingers must be left free. Passive movements of the fingers are begun at once and persevered in. Passive movements of the wrist are begun after five or six days, but the patient must not be allowed to use the hand for a month.

Metacarpo-phalangeal Joint of Thumb.—The first phalanx passes backwards on to the dorsum of the head of the metacarpal bone, which projects into the palm of the hand. The tendon of the long flexor muscle may become hitched round the neck of the metacarpal bone, which is also embraced by the short flexor tendons and the torn glenoid ligament.

REDUCTION may usually be accomplished by the following method (*Fig. 19*): An assistant fixes the hand and metacarpal bone. The surgeon then grasps the thumb and bends it back to a right angle. He then drags upon it in its hyper-extended position, at the same time pressing the head of the metacarpal backwards. Having thus “unlocked” the displacement, he draws the base of

the phalanx forwards until it is level with the end of the metacarpal, and then rapidly flexes the thumb into the palm. Traction upon the thumb may be rendered easier by employing a clove-hitch of soft bandage, or one of the special instruments sold for the purpose. If reduction by this method fails, a tenotome, with the sharp edge towards the extremity of the thumb, is introduced

in the middle line behind the joint just above the base of the phalanx. The point of the knife is then made to pass onwards towards the palm between the short flexor tendons. Next the blade is made to cut on to the base of the phalanx, thus dividing the glenoid ligament, which, running across between these tendons, is the chief obstacle to reduction.

Hip.—When the head of the femur is dislocated from the acetabulum, it follows, as a rule, certain definite paths, and comes to lie more or less exactly in one of four positions. These are known as the four “regular” dislocations. It may be, however, that the severity of the injury is such as to cause very great and widespread laceration of the soft parts around the joint. It is upon the comparative integrity of these soft parts, and more especially of the Y-shaped ligament of Bigelow, that the regular course of the displaced head depends. If

Fig. 20.—Reduction of Dislocation of Hip by Method (1).

this ligament be ruptured, the head of the femur may assume almost any position around the acetabular cavity, or even remote from it. The limb assumes no definite position, movements may be abnormally free and flail-like, and there is usually little difficulty in reduction. These latter are known as the “irregular” dislocations, and will not be further dealt with.

REGULAR DISLOCATIONS.—

(1) *Dislocation on to the Dorsum Ilii*: the limb assumes a position of flexion, adduction, and internal rotation. The head of the femur may be felt above and behind the acetabulum. *N.B.*—When the femoral head is forced directly back, the displacement may be associated with a fracture of the posterior margin of the acetabulum. (2) *Dislocation into the Sciatic Notch*: flexion, adduction, and internal rotation are all present, but are less marked than in the preceding class. The head of the bone is behind the acetabulum, but owing to the greater thickness of the gluteal muscles it is

less easy to feel. (3) *Dislocation into the Thyroid Foramen*: the limb is to a slight extent flexed, abducted, and externally rotated. The head of the bone may sometimes be felt in the perineum. (4) *Dislocation on to the Pubic Bone*: flexion, abduction, and external rotation are each rather more marked than in the thyroid displacement, whilst the head of the bone is readily felt lying beneath or above Poupart's ligament.

REDUCTION.—The patient lies on his back on a mattress placed on the floor, and is anæsthetized.

For Dislocations on to the Dorsum Ilii or into the Sciatic Notch, the following methods should be tried: (1) The surgeon stands near the foot of the patient, facing his head; he grasps the affected limb with one hand below the knee, with the other at the ankle (*Fig. 20*); he then fully flexes the hip, maintaining the adducted position, and next abducts, externally rotates, and finally extends the limb with one sweeping movement. It sometimes happens that this method fails, a click being felt as the movements of abduction and external rotation are being carried out, indicating that the head has once more slipped back into its former dislocated position. In these circumstances the following plan should be tried. (2) The Surgeon stands over the patient, facing his head, and flexes the hip-joint to a right angle. The flexed leg of the patient is between the thighs of the surgeon (*Fig. 21*), who bends forward and folds his forearms beneath the patient's knee. Then, whilst an assistant holds the pelvis firmly down to the mattress, the surgeon exerts strong traction directly upwards.

For Thyroid and Pubic Dis-

locations.—(1) The surgeon, grasping the leg as in method (1) above, flexes the thigh in its abducted position. With one continuous movement he then internally rotates and adducts the limb, finally extending and bringing it down beside its fellow. (2) Thyroid dislocations may be reduced in a manner similar to method (2) above, the limb being, however, slightly abducted, and traction exerted in an upward and outward direction.

After-treatment.—The patient is kept in bed for a fortnight with a Liston's long splint applied. At the end of this time massage is begun, and passive movements are carried out daily. Active movements are allowed a week later, and at the end of a month the patient may be allowed up on crutches. Work may be resumed as a rule at the end of two months. When there has been extensive laceration of muscles and ligaments, weakness of the limb and lameness may continue for a long time; whilst should the sciatic nerve have been injured, there may be paralysis and wasting of muscles. Massage, movements, and galvanism should then be employed assiduously. In the cases referred to where there is a fracture of the acetabular margin, there is a tendency for the dislocation to return, and rest must be considerably prolonged.

Knee.—Displacements rarely occur at this joint. The tibia may pass forwards, backwards, or laterally. The latter is the more common variety, the displacements being usually incomplete, and the border of the tibia resting between the condyles of the femur.

REDUCTION should be performed under an anæsthetic. The thigh is flexed,

Fig. 21.—Reduction of Dislocation of Hip by Method (2).

and traction is made upon the leg. The replacement is aided by direct manipulation and by rotation of the limb.

After-treatment.—The limb is placed on a back splint for three weeks, and passive movements are then begun. Permanent weakness of the joint is apt to remain, and there may be persistent œdema of the foot and leg.

Patella.—This is a very rare dislocation. The patella usually passes outwards, so as to lie upon the external condyle.

REDUCTION.—Flex the thigh fully on to the abdomen, and extend the knee. The extensors being thus relaxed, direct manipulation effects replacement.

Unreduced Dislocations.—In cases of old-standing unreduced dislocations of the patella, generally due to genu valgum rather than to injury, excellent results are given by transplanting the tubercle of the tibia, with the insertion of the ligamentum patellæ, from the front to the inner aspect of the bone.

Ankle.—Lateral dislocations do not occur without fracture, and are considered under the heading of Pott's Fracture of the Fibula (see FRACTURES). The backward dislocation is commoner than the forward, and may be accompanied by fracture of one or both malleoli.

REDUCTION is affected by pulling upon the foot, with the knee fully flexed to relax the gastrocnemius (*Fig. 22*). If this be ineffectual, even under an anæsthetic, the tendo Achillis should be divided subcutaneously.

Fig. 22.—Reduction of Dislocation of Ankle.

After-treatment.—The limb is put on a back splint with a foot-piece, care being taken to keep the foot at a right angle. Massage is begun after three days, the splint being removed for the purpose. The splint is dispensed with at the end of three weeks.

Astragalus.—The astragalus, when dislocated, is displaced both from the tibio-fibular mortice and from the upper surface of the os calcis. The dis-

location may be complete or incomplete, in the former case being often compound. **REDUCTION** may be sometimes accomplished in the incomplete forms. An anæsthetic is given, and direct pressure in the requisite direction is made on the astragalus whilst the foot is firmly pulled upon. During these manipulations the knee is well flexed to relax the tendo Achillis, or that structure may need division. In the complete forms reduction is impossible, and excision of the astragalus should be performed through a free incision.

After-treatment.—The limb is put on a back splint, the foot being kept at right angles. Massage is begun after three days, and passive movements after a fortnight. When the astragalus has been excised, massage and movements are commenced as soon as the wound is firmly healed.

Subastragaloid Dislocation.—In this injury the astragalus retains its position with regard to the tibia and fibula, whilst all the other bones of the foot are displaced from beneath it, usually in a backward direction.

REDUCTION should be attempted by pulling the foot forwards whilst counter-pressure is made on the front of the lower end of the tibia. During this procedure an assistant keeps the knee well flexed. In difficult cases the tendo Achillis, and possibly also the tibial tendons, may need division. When reduction fails, the astragalus should be excised. This will admit of the foot being placed in a fair position.

After-treatment should be carried out as for dislocation of the astragalus.

Spine.—(See SPINE, FRACTURES AND DISLOCATIONS OF.) *S. Maynard Smith.*

DISSEMINATED SCLEROSIS.—The treatment of disseminated sclerosis is most unsatisfactory; indeed it is doubtful whether recovery or permanent arrest ever takes place. Since the pathology of the disease remains obscure, it follows that no rational line of treatment is available, while therapeutic deductions are necessarily very difficult, because of the remissions which are apt to occur quite apart from intervention. The first aim in treatment consists in the avoidance of influences which experience has shown to have a deleterious effect. Fatigue especially is to be guarded against, although prolonged rest in bed is not advisable. In the case of married women, the dangers of childbearing are to be clearly pointed out, for there can be no question that the disease is often greatly aggravated by pregnancy. Sufferers from disseminated sclerosis should be warned as to the risk of exposure to infectious diseases, and particularly to influenza.

No known drug is universally admitted to modify the course of disseminated sclerosis. Among the many remedies, the effects of which have been from time to time extolled in this disease, arsenic has perhaps been most largely used. The writer is inclined to think from his experience that this drug is, at times, undoubtedly of value. It may be conveniently given in doses of from two to six minims, three times a day, and its administration should be continued for several months. Silver nitrate and potassium iodide are, it is affirmed, sometimes of value. Risien Russell is "satisfied that many cases improve under inunctions of mercury, provided that this treatment is combined with a great deal of physical rest and a liberal diet modified on the lines adopted in a rest cure." Judson Bury has "thought that the administration of suprarenal extract has done good." Neither fibrolysin nor salvarsan appear to be of use. Strychnine is contra-indicated, since it undoubtedly tends to increase the spasticity. It is very doubtful whether electricity is of the slightest value, while it is also open to question whether the x rays are of any service. When spasticity is pronounced, it may sometimes be relieved by massage and passive movements. Veronal may be found to be occasionally helpful in alleviating the flexor spasms in the lower extremities which are at times so troublesome. In the later stages, the usual precautions are to be taken to avoid the occurrence of bedsores and cystitis. (See PARAPLEGIA.)

Edwin Bramwell.

DIVERTICULITIS OF THE COLON.—This condition is often described under the heading pericolicitis, or pericolicitis sinistra. It is a curious condition, characterized by the formation of small pouches or hernial protrusions of the mucous membrane of the colon through its muscular walls. These protrusions vary from minute canals to quite large tubes resembling the appendix or a Meckel's diverticulum. They usually find their way into the appendices epiploicæ, or between the layers of the mesocolon. Fæcal material gradually spreads from the bowel lumen into these pouches, and the apex of each pouch generally contains a fæcal concretion. In a well-marked case of this disease many hundreds of these pouches may be found in quite a small section of the bowel. As a rule the disease is confined to elderly subjects, and appears to be the direct result of chronic constipation. It most commonly occurs in the lower part of the colon, and particularly in the sigmoid flexure. Inflammatory changes, with subsequent fibrosis, take place in the wall of the affected bowel, and in course of time a considerable degree of stricture and tumour formation occurs. The condition is frequently mistaken for malignant disease of the large intestine. Occasionally one of these pouches ruptures, with the consequent formation of an intra-abdominal abscess, or acute general peritonitis. The diagnosis can sometimes be established by means of the x rays or the sigmoidoscope.

The only treatment, apart from operation, offering any hope of amelioration,

consists in keeping the contents of the colon as soft as possible by the administration of petroleum by the mouth, assisted by the use of aperients and enemata. The proper treatment for this condition is resection of the affected portion of the large intestine. This is, however, often impossible owing to extensive adhesions to surrounding structures. When resection is impossible, the affected portion of the colon should be short-circuited, either by lateral anastomosis or by an ileo-sigmoidostomy. If the disease is situated so low down as to negate both of these alternatives, colotomy should be performed in healthy bowel above the tumour.

J. P. Lockhart Mummery.

DROPSY, CARDIAC.—(See HEART, VALVULAR DISEASES OF.)

DROPSY, RENAL.—Certain forms of chronic renal disease are accompanied by dropsy, and in many instances, but not in all, this calls for treatment apart from the general treatment of the disease. Dropsy in renal disease may be purely of renal origin, but in some instances it is of secondary cardiac origin and associated with cardiac dilatation, the result of so-called failing compensation.

Whether the dropsy be renal or cardiac in origin, it is always accompanied by a diminution in the flow of urine. This diminution, however, is not always the cause of the dropsy, and it is a most important point as regards the treatment of the condition, for the question whether diuretics should or should not be given turns on the question whether the scanty flow of urine is the cause or the result of the dropsy. It is useless to give diuretics if the condition of the kidney is such that it is unable to eliminate water; on the other hand, diuretics may be of some service if the dropsy is dependent on a primary blood-change leading to increased transudation of fluid through the walls of the vessels. It certainly cannot be said that diuretics are always contra-indicated in chronic Bright's disease associated with dropsy. At the same time, treatment should be directed, not only to promoting the excretion of water by other channels, in addition to the kidney, but also to preventing as far as possible the development of the dropsy itself.

The promotion of the excretion of the dropsical fluid by other channels than the kidney, for instance the bowels and the skin, necessitates the re-absorption of the dropsical effusions into the blood-stream, and these dropsical effusions contain large quantities of toxic material. Thus it is not as a rule advisable to employ measures which act suddenly and violently, to effect this purpose. There is a considerable amount of evidence to show that the quantity of chlorides present in the food and in the blood-stream has a material influence in increasing any dropsy present, and possibly may even cause it. The urine, in cases of tubal nephritis associated with dropsy, may eliminate chlorides with difficulty, and it has been shown that the administration of chlorides to these patients is liable to be followed by an increase in the dropsy. This increase may not only be detected by physical examination, but it is often sufficiently rapid and marked in amount to show itself by an increase in the body-weight of the patient. It is not difficult to restrict the amount of chlorides in the food, by avoiding their use as a condiment in cooking, and by ordering a diet that is poor in chlorides. In some cases of chronic nephritis with persistent dropsy, very beneficial results may be seen to follow the restriction of the amount of chloride of sodium in the diet, and in some cases the dropsy may entirely subside with a diet reducing the intake of sodium chloride to a minimum. Bread made without salt must be used, and the bulk of the food must consist of vegetables cooked without salt, but meat may be allowed provided always that no salt be taken with it. Certainly this method of treatment would seem desirable in cases where dropsy is marked and increasing. Although it is useless to treat

dropsy by an undue restriction of the amount of fluid ingested, it is often useful in chronic cases to avoid giving large quantities of milk and other fluids which may lead to the production of a hydræmic plethora, and such patients may do better on a diet of solid food, meat and bread.

The excretion of water by other channels than the kidney must be promoted by moderate purgation, as already explained, and, to a limited extent, by measures directed to bring about sweating. In chronic renal disease it is often difficult to produce sweating, and generally the best results are obtained by moderate measures, such as warm or hot-air baths, where the temperature is not unduly raised. Uræmic symptoms, and even fatal uræmia, have been known to occur as a result of the indiscriminate use of hot-air baths of high temperatures, and it is possible that such effects may result from the sudden absorption of large quantities of the dropsical exudation associated with the copious sweating. Hot-air baths should be used with the idea rather of promoting a gentle action of the skin than of procuring the subsidence of large dropsical effusions. Pilocarpine is sometimes recommended in such cases, and it is of course possible to produce profuse sweating by this means; but there is always the risk of causing considerable pulmonary embarrassment, owing to the copious secretion from the bronchial tubes seen under the influence of this drug, and in free doses it may also lead to the development of cardiac weakness, and on the whole its use is not to be recommended for the relief of dropsy.

Very striking results can often be obtained by the use of diuretics. Acetate, citrate, and nitrate of potash are of service, but one of the most useful diuretics in chronic renal disease is caffeine, provided it be used in small doses and intermittently. Caffeine is a powerful diuretic; but its action is peculiar in the fact that the best diuretic results are seen when small doses are given. Large doses, and frequently repeated doses, tend to produce an opposite effect to that seen with small quantities, and it is not uncommon, where the drug is continually administered, for a diminution in the amount of urine to occur, associated with the development of headache, sickness, and other unpleasant symptoms. Caffeine in very large doses may even produce suppression of urine, and this is not an uncommon result in the laboratory after its experimental administration. Clinically, it not uncommonly produces a diminution in the flow, together with headache and vomiting. If the drug is administered in small doses and intermittently, only good results are obtained. It may be given in 5-gr. doses of the citrated every four hours for three or four doses; the administration should then be stopped for twenty-four or forty-eight hours, and then the drug given again. In this way a notable diuretic effect may be produced. It is often useful to combine with the citrated caffeine small doses of digitalis, which, although not a diuretic in the strict sense of the term, may produce an increased flow of urine, thanks to its action in improving the circulation. Digitalis is not always advisable in cases of renal disease associated with considerable high tension, owing to its well-known action in increasing the blood-pressure. Indeed, in all cases of chronic Bright's disease, the administration of diuretics must be largely determined by the results seen. If the giving of a few doses of caffeine is not followed by any beneficial diuretic effect, no useful purpose is served by persisting in its administration. Broom tops, squills, and other drugs of a similar kind, are often also useful. Where the amount of dropsy is large, and especially where it is refractory to treatment along the lines indicated, it is best to remove the fluid by Southey's tubes. There is no objection to the use of these in renal disease, provided care be taken to make and treat the punctures aseptically. In cases of generalized anasarca, with fluid in the pleural and peritoneal cavities, puncture of the legs with Southey's tubes is often sufficient to procure relief generally but if this is not the case, the collections of fluid

in the chest should be removed by paracentesis, which should be performed slowly, owing to the well-known tendency to the development of pulmonary œdema in this disease and the risk of this complication occurring as a sequel to the too rapid drawing off of a pleural effusion. (See also NEPHRITIS.)

J. Rose Bradford.

DROWNED, TREATMENT OF THE APPARENTLY.—Place the patient face downwards on the ground, preferably with a folded coat under the lower part of the chest. Do not lose time in attempting to remove his clothing. Begin artificial respiration by the Schäfer method as follows:—

1. Place yourself athwart or on one side of the patient's body in a kneeling posture and facing his head.

2. Place your hands flat over the lower part of the back (on the lowest ribs), one on each side, and gradually throw the weight of your body forward on to them so as to produce firm pressure—which must not be violent—upon the patient's chest.

3. Raise your body slowly so as to remove the pressure, but leaving your hands in position.

4. Repeat this forward and backward movement every four or five seconds.

This course must be pursued for at least half an hour, or until the natural respirations are resumed. When breathing has been established, the patient may be turned on his back and active means employed to promote the circulation, by friction of the limbs in a direction towards the heart, and by the application of hot flannels, hot bottles, etc. As soon as the patient can swallow, small quantities of wine, warm brandy and water, beef-tea, or coffee may be administered. He should then be put to bed and encouraged to sleep.

Robert Hutchison.

DRUG HABIT.—The most important drug habits are the abuse of morphine and cocaine. Alcoholism is dealt with in a separate article. The cocaine habit is even more serious than the morphine habit, and more difficult to eradicate.

In the treatment of morphinomania or cocainomania it is a *sine qua non* that the patient should be removed from his own home to some special institution where he can be under continuous observation and control. Nothing must be left to the patient's own good-will. If left to himself, he will break the most solemn pledges with the utmost callousness.

One has then to decide whether an attempt shall be made to stop the drug suddenly, or whether its dose shall be gradually reduced day by day. Experience shows that sudden stoppage is rarely tolerated, and is only feasible in the mildest cases, where the habit has been of comparatively short duration, and the dose has not been large.

Even the "rapid" method, where the dose is reduced progressively so as to reach zero within six or twelve days, causes the patient great distress, though less than by the sudden method. Best of all—in the absence of specific treatment by hyoscine, to be described presently—is the gradual method, in which some six weeks are occupied in reducing the dose to zero. One way of accomplishing this is to make a solution, say 1 oz., of the full strength of the drug to which the patient has been accustomed, and for every syringeful withdrawn from the bottle, to replace a corresponding quantity of boiled water. The strength of the solution is thereby gradually reduced until at last the patient gets an infinitesimal dose of the drug.

During the process of demorphinization or decocainization, one of the chief difficulties is insomnia. To combat this it is usually necessary to administer hypnotics. For this purpose one may employ full doses of trional, 30 or 40 gr. at a time. Or one may follow Neil Macleod and deliberately induce bromide

poisoning by enormous doses of sodium bromide, up to 1 oz. twice daily. A state of narcosis is thus produced, from which the patient awakes, probably in an excited, delirious condition, but having lost his craving for the drug. By this method it is claimed that three days are often enough to produce the full effects.

But amongst physicians who have opportunities of observing the progress of morphine *habitués*, it is the universal experience that treatment by simple withdrawal of the drug, however gradually this be done, is always associated with intense suffering to the patient. And it must be admitted that the percentage of cures thus obtained is not a large one. Within recent years, however, a more efficacious method of treatment has been elaborated, which consists essentially in the administration of massive doses of hyoscyne, pushed to the point of producing a mild delirium.

Briefly the routine pursued is as follows: The patient must be secluded in a special home, in a quiet room, away from other patients. He is put to bed, and reliable nurses must be in constant attendance day and night for the first few days at least. The medicinal treatment commences with $\frac{1}{100}$ gr. of hyoscyne hydrobromate hypodermically. Every hour after this, for twenty-four to forty-eight hours, $\frac{1}{200}$ gr. is administered, watching carefully the pulse and respiration. As a result, symptoms of hyoscyne intoxication supervene. They resemble those of the other members of the belladonna group: the pupils become widely dilated, the tongue and throat very dry, and within twelve hours or so the patient develops a mild restless delirium, accompanied by choreiform movements, picking at the bed-clothes, and by visual hallucinations referred to various parts of the room. Such visions as a rule are not disagreeable to the patient. When this stage is reached the hyoscyne is continued just often enough to maintain the delirium for twenty-four or forty-eight hours (from $\frac{1}{200}$ to $\frac{1}{100}$ gr. every two or three hours during this period). After this the hyoscyne is stopped, and the patient, when his delirium comes to an end, has lost his craving for morphine. During the early part of the hyoscyne period, it may be necessary to give a small dose of morphia, $\frac{1}{4}$ gr., once or even twice. This will not affect the ultimate result. As a rule, hyoscyne alone is all that is required. Strychnine may, however, be added ($\frac{1}{60}$ gr. occasionally) to sustain the heart, if necessary. During the period of delirium, the patient should have water to drink, to relieve the dryness of his mouth and throat.

After thirty-six or forty-eight hours of artificial hyoscyne delirium, the drug is discontinued, and in a few hours the patient is mentally clear again. Then begins a second phase of the treatment, which consists in regular hypodermic administration of pilocarpine, $\frac{1}{8}$ gr. every hour, to produce sweating, and thereby to favour elimination of the hyoscyne, gradually increasing the intervals between the pilocarpine injections. Joint pains, especially in the knees and elbows, also pains in the back, and diarrhoea, tend to develop at the end of this period. The diarrhoea is checked by a mixture containing bismuth salicylate 60 gr., with fluid extract of coto bark 6 min., suspended in mucilage or syrup. The pains are alleviated by massage, hot baths, or galvanism. If the patient is sleepless, 30 gr. of bromide of potassium, combined, if necessary, with 10 gr. of chloral hydrate, may be required. After the pilocarpine stage is over, great benefit is obtained by general massage daily for a fortnight. Bromaurum, in 10-min. doses thrice daily, is also of distinct advantage, and should be persevered with for two or three months.

The results of such treatment have been most gratifying. It necessitates, however, careful supervision by the physician. Certainly, by this method the danger of collapse from withdrawal of morphia is obviated. And the large number of successful cases which have now been recorded has been sufficient to place the method beyond the experimental stage.

Purves Stewart.

DUODENAL ULCER.—When duodenal ulcer has been diagnosed, the first question that arises is, should the case be treated by operation? Although some surgeons regard every case of duodenal ulcer as requiring operation, the opinion more generally held is that if the symptoms be not of long duration, if there be no evidence of obstruction in the duodenum, and if there has not been any hæmorrhage, a course of medical treatment should first be tried. Such treatment is as follows: The patient must go to bed for at least three weeks. During the first week hot fomentations, changed every two hours, should be applied to the abdomen; during the night cotton-wool and a binder may be worn. The diet in the first week should consist of milk (8 oz. every two hours from 8 a.m. till 10 p.m.), with two beaten-up eggs in the day. In the second week the fomentations may be discontinued, and Benger's food, custard, jellies, and boiled rice added to the diet. In the third week, lightly-cooked eggs, fish, and chicken panadas may be allowed, with stale bread or rusks. The food should be arranged in three meals with milk between, and an ounce of cream should be given before each of the chief meals. From the beginning of the treatment a moderate-sized teaspoonful of a powder consisting of equal parts of bicarbonate of soda, bismuth carbonate, and heavy carbonate of magnesia should be given in a little milk, four times a day. If this renders the bowels too loose, the magnesia may be omitted, and if there be constipation, a teaspoonful of Carlsbad salts may be given in a tumblerful of warm water every morning. After three weeks of such treatment the patient is allowed up on a couch, and then gradually begins to get about, and later, should go away for a change. For some months afterwards the diet must be very simple and unirritating, all indigestible articles and sour or highly seasoned foods, as well as alcohol and tea, being avoided; and bismuth should be taken regularly to prevent hyperacidity of the gastric juice. Attention must also be paid to careful mastication, to the hygiene of the mouth, and to the avoidance of chill and over-fatigue.

The above may be regarded as the routine "cure" for such a case, and if after its thorough employment the symptoms recur with any severity, operation should be advised.

A special method of treatment has been advocated by Hort, which consists essentially in giving a full meat diet (to "fix" the acid of the gastric juice), with the administration of a special antilytic horse-serum (Allen & Hanburys) in 10-min. doses in $\frac{1}{2}$ ounce of water by the mouth, on a full stomach, four times a day (to counteract the digestive action of the ferments). In all severe cases the use of the serum should be continued for six weeks. Complete rest in bed for two or three weeks is insisted on. As regards diet, no milk, soup, or fish in any form, is allowed from first to last. For the first three or four days small meals are given every three hours during the day; no meals at night. These consist, in rotation, of small quantities of stale bread, the yolks of lightly cooked eggs, and panada or quenelle of chicken. The only liquid allowed is 10 oz. of hot water at 7 a.m., 11 a.m., and 10 p.m. If all goes well, at the end of four or five days the dietary is doubled in quantity. On the seventh or eighth day pounded meat, lightly cooked, is added. By the end of the second week, meat forms the chief food, and the meats chosen are beef and mutton. In three weeks from the commencement of treatment full diet is generally well borne, but alcohol, soup, tea, coffee, and all starchy puddings, are forbidden for six months. The writer has had no experience of this method of treatment.

As regards complications, *perforation* of course calls for immediate operation. *Hæmorrhage* should be treated on the same lines as hæmatemesis (q.v.), food by the mouth being withheld and a pint of normal saline given by the bowel twice a day. Morphia may be used for restlessness. Styptics are of doubtful utility, but adrenalin in 10-min. doses (1-1000) may be tried by the mouth,

and 20 gr. of calcium chloride added to each enema. Gelatin has also been recommended: 5 dr. of gelatin should be boiled in water for six hours, and the solution brought up to 5½ oz. It should remain fluid, and when cold be filtered, and 30 gr. of citric acid added. One or two teaspoonfuls of this may be given every two hours. Sterile horse-serum in 10-c.c. doses subcutaneously is also believed to be of value.

Should the bleeding persist, or the patient begin to show any signs of exhaustion, operation should be performed.

Robert Hutchison.

DUODENAL ULCER (Surgical Treatment). (See also under STOMACH.)—These patients have usually suffered for years before coming under surgical supervision. To attempt to cure by medical treatment is futile; delay should not be countenanced—the danger of perforation in cases of chronic duodenal ulcer is considerable.

Treatment consists in infolding the ulcer and performing a posterior no-loop gastrojejunostomy. At the same time the whole abdomen should be thoroughly explored, and any disease found dealt with. This applies particularly to the gall-bladder, appendix, and ileocaecal region. Great care should be exercised in the after-treatment; the patient should not be hurried to return to solid food, but rather restrained, and every effort made to keep gastric acidity low. If this was excessive before operation, it is wise to examine again at the end of three months to see if the measures that are being taken are efficient. Patients after operation are apt to over-indulge, particularly if they have been dieted, and unable to take their usual food without great discomfort.

Hæmorrhage.—This is a late and serious complication of a chronic duodenal ulcer. If severe, operation should be carried out as soon as possible after the first hæmorrhage; this is usually within thirty-six hours. In these cases the ulcer is generally situated on the posterior wall, and the gastroduodenal or superior pancreatico-duodenal artery is the source of the bleeding. The anterior wall of the duodenum should be infolded, and the gastroduodenal artery tied; or, if from the presence of coincident anterior ulceration or adhesions this cannot be satisfactorily performed, the gut should be opened and the vessels tied. Posterior gastrojejunostomy should always be performed at the same time.

Perforation.—The ulcer which perforates is usually a chronic one. In many of my cases the patient had been under treatment for a considerable time.

There are two types: those in which the diagnosis of perforation of a peptic ulcer is certain from the sudden onset of symptoms; and those in which the onset is more gradual, the symptoms which bring the patient under observation being those of a subphrenic abscess, or resembling somewhat those of appendicitis.

Operation should be carried out at once, the perforation closed, and posterior gastrojejunostomy performed, except in the rare instance of the perforation of an acute ulcer or in late cases where the extra time necessary is of serious moment. After examining for further perforations, any extravasated fluid should be gently wiped away and the abdomen closed. If there is much peritoneal soiling, the right kidney pouch, and if necessary the pelvis, should be drained.

In all my patients in whom a gastrojejunostomy was not done at the time of closure of the perforation, this had to be carried out later for recurrence of symptoms. I have also had to do this in five cases after the perforation had been closed by other surgeons. If drainage has been necessary, the tubes can usually be removed within thirty-six hours. If for any reason it was impossible to perform gastrojejunostomy at the first operation, and the ulcer was a chronic one, this should be carried out later.

James Sherren.

DUPUYTREN'S CONTRACTION OF THE PALMAR FASCIA.—This is a disease peculiar to adult life, occurring in fact more commonly in persons over the age of thirty-five. It affects men much more frequently than women. The deformity produced is one of flexion of the fingers, first of all at the metacarpophalangeal, and later on at the interphalangeal joints, so that the fingers become drawn up into the palm of the hand. There is not, as a rule, much flexion of the terminal phalanges. The digits chiefly affected are the ring and little fingers, and usually the disease is confined to these; but cases are recorded in which all the fingers, and even the thumb, have been involved.

The diagnosis is by no means difficult, as the deformity is so typical. It is distinguished from contraction of the flexor tendons by the fact that the flexion of the fingers remains the same in every attitude of the wrist, whereas in the latter condition dorsiflexion of the wrist increases the palmar flexion of the fingers. Contractions due to suppuration, traumatism, or burns, are readily detected after reference to the history of the case. In congenital flexion of the fingers, the interphalangeal joints are chiefly affected, and the patient is usually a child, or can remember the deformity from early childhood. Transient or incomplete ulnar paralysis may cause the ring and little fingers to assume an attitude not unlike that of a mild Dupuytren's contraction, but the metacarpophalangeal joints are not flexed, and there is no resistance to passive movement in the direction of extension.

TREATMENT may be (1) Non-operative, or (2) Operative.

Non-operative Treatment.—There is no doubt much may be done for early cases of Dupuytren's contraction by persistent massage, passive movements of the fingers, and the employment of suitable absorbent ointments, containing a salt of mercury, iodide of lead, or iodide of cadmium. With these measures, combined with the application of a good splint at night, a mild case can be prevented from becoming worse, and may even be cured if the treatment be carried on for a sufficiently long time. The splint employed by the writer is a simple metal one, composed of a broader hand-piece, making an angle with a narrower portion which is applied to the forearm; when the splint is in position, the wrist is dorsiflexed. The splint can be bent so that the angle of dorsiflexion is diminished or increased as the surgeon wishes. It should be well padded, and applied to the front of the hand, the fingers being straightened out upon the hand-piece as much as possible, and kept in position by padding and bandages. It is inadvisable to exercise much pressure upon the fingers, as sloughs form very readily upon the tips of the fingers and the backs of the knuckles, and therefore correction of deformity should be gradual.

Operative Treatment.—Where there is much deformity, operation is imperative, and the operative procedure may be either subcutaneous—fasciotomy with a fine tenotomy knife—or removal of the fibrous bands through an open incision. The subcutaneous operation is the one most advocated in this country, and the results to be obtained are most satisfactory. All the tight bands are divided with the tenotome through, it may be, many punctures in the skin. The edge of the knife is directed away from the surface, the blade being insinuated so as to separate the skin from the subjacent fibrous tissue. The puncture should not be made in any of the transverse creases in the palm, and care should be taken not to damage the skin over the fibrous knot. As a rule it will be necessary to divide one or more bands in the palm, and the slips which run to the side of the first joint of each finger: in dividing these processes the digital nerves should not be injured, or the vitality of the fingers is impaired. It is inadvisable and unnecessary to correct all the deformity at one sitting, as the pressure upon the knuckles and tips of the fingers would be too great when the hand is splinted. The metacarpophalangeal joint can usually be fully extended at once, and the

others gradually straightened in the succeeding week or ten days. The hand and fingers must be freely exercised and massaged, and the splint retained until the patient can keep his fingers fully extended and the wrist dorsiflexed with his own muscular power. Even then he should continue to wear his splint at night and keep a sharp look-out for any return of the deformity.

The open operation may be a plastic section of the skin and fibrous tissue as devised by Busche, who makes a V-shaped incision in the palm, and unites it so that it forms a Y. Goyrand and Kocher turn back a flap of skin, and dissect out the bands of fibrous tissue underneath, grafting, if necessary, any raw area which may be left after the deformity has been corrected.

Robert Jones.

DYSENTERY.—Under this name are included several conditions, distinct probably both as regards etiology and the nature of the lesions produced. Various diseases of the anus and lower part of the rectum are frequently mistaken for dysentery. These include malignant and other chronic diseases of the rectum, fissures, fistula, and bilharzia disease. In such conditions appropriate surgical or other treatment is required.

Acute Dysentery.—Rest in bed, warmth, and low diet are necessary. The diet should be restricted to milk, diluted with one-fourth barley- or rice-water, and given in small quantities, 4 oz. only at a time. Arrowroot, made rather thick, is of decided value. Meat is more deleterious than vegetable food; even green vegetables can be taken with impunity when meat would cause a relapse. If abdominal pain or griping be severe, large hot fomentations should be applied to the abdomen. Straining at stool is to be discouraged. The two main lines of medicinal treatment are by (1) *Ipecacuanha* and (2) Saline aperients.

1. *Ipecacuanha Treatment.*—Large doses should be given, 15 to 30 gr., repeated after eight hours. Some practitioners give a single dose only on the first day.

In order to check the vomiting, the patient must be kept absolutely at rest; no food or fluid should be given for an hour or more before the administration of the drug. He must be instructed not to swallow his saliva. Laudanum (15 min.) or chloral hydrate (20 gr.) should be given, twenty minutes before the *ipecacuanha* is administered. The *ipecacuanha* may be made up into conveniently sized pills, which may be coated by dipping into melted salol, or the *ipecacuanha* powder can be suspended in water or dilute syrup, and swallowed. If vomiting result, the dose must be repeated. Where vomiting occurs regularly after the administration of the drug, this may be given as “membroids.” The vomiting may still occur, but only after some hours, and in this time much of the effect of the drug has been produced. Sometimes these membroids are passed unchanged. Sinapisms applied to the epigastrium further tend to check the vomiting. On the following day the dose may be reduced by 5 gr. and given once, with the same precautions. In a case progressing favourably, the amount of *ipecacuanha* given can be reduced by 5 gr. daily. It is well to continue the daily administration of small doses (5 gr.) for some time after apparent convalescence. Return to an ordinary diet must be gradual, and large meals of any kind avoided. Emetine hydrochloride in $\frac{1}{4}$ to $\frac{1}{2}$ -gr. doses, given as an intramuscular injection or in keratin-coated capsules, has largely replaced the big doses of *ipecacuanha*. These doses of emetine should be given daily for one or two weeks, and be followed by the prolonged administration by mouth of small doses (2 to 5 gr.) of *ipecacuanha* in pills.

2. *Treatment by Saline Aperients.*—The use of this method of treatment is steadily increasing. In principle it aims at securing a steady intestinal flush with a minimum of discomfort. A convenient method is to give 2 or 3 dr. of a saturated solution of sulphate of soda with 5 min. of dilute sulphuric acid, in a wineglassful of water, every two hours till a liquid fæculent motion is passed,

and then increase the intervals between the doses to four or six hours. After the first two days, a dose once or twice a day will suffice. Intestinal antiseptics, such as β -naphthol 10 gr., salol, etc., may also be given. Some practitioners prefer smaller doses of either sulphate of soda or magnesia, at first given hourly. Castor oil or olive oil in full doses, with 10 to 15 min. of laudanum, is preferred by others, and gives satisfactory results in mild cases. Medicinal enemata should not be given in the acute stage.

Serum treatment in the bacillary forms is of great value, but care must be taken that the strain of the bacillus from which the serum is prepared is that with which the patient is infected.

Chronic or Relapsing Dysentery.—Here results are less certain. The same treatment as in the acute cases often gives satisfactory results, but by no means invariably. If either active amœbæ or encysted forms are found, a course of emetine consisting of daily injections for seven to ten days will often be beneficial. The relapses are often due to dietetic errors, and frequently to constipation. Constipation after dysentery is not easy to deal with. In many cases it appears to result from an atonic condition of the intestines. Natural waters sometimes suffice. Cascara sagrada and belladonna are more trustworthy. The fluid extract of cascara (5 to 10 min.) with tincture of belladonna (6 min.) in an ounce of chloroform water every night, will often relieve the condition; the dose may then be steadily reduced. In some cases rectified petroleum is most suitable, at first in frequent doses, such as 2 dr. t.d.s., and then as a single nightly dose of 1 dr. to $\frac{1}{2}$ oz.

Bismuth and astringents are of considerable value where diarrhœa occurs with or without mucus. Opium, in any form, must be used cautiously, as the condition of the intestine is often atonic. Increase in flatus often follows its administration, and then it may even aggravate the condition.

In the severer chronic forms, large enemata, given with a long soft flexible tube, are sometimes employed. Before giving these, the intestines should be washed out with a large (2-pint) enema of weak carbonate of soda solution, 20 gr. to the pint. Of these enemata, boracic lotion is of value; nitrate of silver, $\frac{1}{2}$ to 1 gr. to the ounce, and other stimulating lotions, are also used, and in amœbic dysentery, sulphate of quinine. These enemata should be given very slowly, and must be warm (blood-heat). They should be retained for a longer period each day. They should not be long retained if they cause pain. Where the motions are frequent, the old enema opii B.P. 1885 (*i.e.* $\frac{1}{2}$ drachm laudanum and 2 oz. mucilage of starch) with 20 gr. of quinine sulphate suspended in it, is sometimes of great value, as the quinine is slowly dissolved.

Native remedies must not be despised. Most of these are fresh decoctions, such as those of bael fruit or the skins of the mangosteen; they do not seem to be of much value either after drying or solution in alcohol, though successful when freshly prepared. Cinnamon in 5 to 10 gr. doses is used by some, particularly in bacillary dysentery.

Alcohol as a rule is contra-indicated. In intractable cases, surgical intervention—appendicostomy and colotomy—may be advisable. (See also COLITIS and SPECIFIC THERAPY).

C. W. Daniels.

DYSMENORRHŒA.—Dysmenorrhœa in its most typical form is either congenital in its origin, or starts within a year or two after the commencement of menstrual life. In such cases severe pain is felt just before or at the onset of the flow. The severe pain seldom lasts more than a few hours, but may return as the period draws near its close. The pain is spasmodic in character, hence the name spasmodic dysmenorrhœa. In typical cases the patient is quite free from pain in the intervals between the menstrual periods. The pain appears

to depend on painful, irregular spasm of the uterine muscle, and is specially apt to occur in imperfectly developed uteri. The tissues around the os internum sometimes appear to possess a gristly hardness. The size and shape of the os externum have no bearing on the condition. The tissues surrounding the os internum are sometimes very sensitive, and acute pain is then caused by the passage of a uterine sound.

Pain of this type occasionally develops in women who have previously suffered little or nothing, as the result of anæmia or overwork. In such cases rest and a course of iron usually soon set matters right.

Well-marked spasmodic dysmenorrhœa of congenital origin is by no means easy to deal with. The pain may sometimes be relieved by medicinal measures, but their action is somewhat uncertain. Some cases are cured by operation, others only relieved, whilst not infrequently dilatation of the cervix fails entirely.

If the patient be otherwise healthy, perhaps the treatment that most often gives relief is the administration of salicylate of soda in 10-gr. doses, three times a day after meals, for a week preceding each menstrual period, and at the onset of the pain phenacetin or phenazone (*antipyrin*) in 15-gr. doses every hour, until three doses have been taken : with the onset of the pain the salicylate of soda is discontinued. Care should be taken that the bowels are freely relieved at the time when the onset of the period is expected. If the patient is at all anæmic, an ergot and iron mixture, taken for a week before each period, is sometimes more effective than the salicylate of soda.

Bromides are of little or no use, and opium should never be given. Many other drugs have been recommended, and occasionally seem to do good, such as tincture of castor, *cannabis indica*, etc.

If the pain is really very severe, and is not benefited by drug treatment, dilatation of the cervix may be tried. It is important to remember that this does not cure all cases of spasmodic dysmenorrhœa, and it is generally impossible to foretell in any individual case the result of such an operation. Dilatation of the cervix in cases of dysmenorrhœa has to be carried out under an anæsthetic, and the most careful antiseptic precautions must be taken. Graduated metal or vulcanite dilators are used. Hegar's dilators are rather too straight, and increase in size rather too quickly to be convenient in some cases of dysmenorrhœa where the uterus may be a good deal anteflexed. The cervix should be dilated by bougies to a size corresponding with No. 14 on Hegar's scale. When the dilatation is completed it is generally wise to curette the uterus, especially in cases of long standing. It is unwise to pack the uterus, and unnecessary to pack the vagina. Cases which dilatation of the cervix with curetting fails to cure or relieve are generally best advised to put up with their troubles. If on account of the intensity of the pain further operative treatment is called for in a young woman, it is perhaps wiser to remove the uterus and leave the ovaries, rather than extirpate both ovaries and leave the uterus. Neither hysterectomy nor oöphorectomy should be undertaken for this trouble unless the symptoms are unusually severe and all other methods have failed to give relief.

W. J. Gow.

DYSpareunia.—The cause of the pain may be vulval, vaginal, or more deeply situated.

Vulval causes.—Inspection of the vulva may reveal a tender spot, painful red patch, inflamed tag of hymen or hymeneal fissure, vascular caruncle, etc., or the orifice may be too small. For the first four conditions, abstention from sexual intercourse, and application of lead lotion and a soothing dusting powder, such as dermatol, will be sufficient. A vascular caruncle should, of course, be removed. For cases in which the vaginal orifice is too small, *vide* VAGINISMUS.

Vaginal causes.—An acute or subacute vaginitis may be found, for which rest, and soothing douches of lead or boracic acid, should be ordered. A vaginal cyst, if causing dyspareunia, should be removed.

More-deeply situated causes.—Retroversion with tenderness of the body of the uterus, low position of tender ovaries, or inflammation of the tubes and ovaries, may be the cause of severe dyspareunia. For the treatment of these conditions, *vide* the articles on the treatment of retroversion (UTERUS) and of SALPINGO-OÖPHORITIS.

In some cases *tenderness of the urethra* is the cause of the pain. Hyoscyamus may be given internally, and bougies made up with 5 gr. of dermatol in cacao-butter may be inserted into the urethra two or three times a week.

In cases of spasmodic dysmenorrhœa, dyspareunia is common. Dilatation of the cervix is sometimes successful by itself in removing this trouble; in other cases the vaginal orifice is too narrow.

Incomplete intercourse seems to be responsible for some cases of aching in the pelvic organs and dyspareunia. If no cause can be found, a cacao-butter pessary containing cocaine may be tried. (See also STERILITY.)

H. Russell Andrews.

DYSPEPSIA.—The treatment of the different varieties of dyspepsia is considered in detail in various articles, but it is proposed to discuss here some general principles applicable to all cases.

At the outset it must be clearly realized that treatment is not likely to be satisfactory unless some attempt be made to ascertain the precise form of stomach derangement with which one has to deal. Failure to attain success is usually due to neglect of this rule. It will be necessary, therefore, to make a few preliminary observations on the subject of differential diagnosis.

In the first place, it must be remembered that in many patients who complain of "indigestion," the seat of the trouble is not really in the stomach at all.

Any of the three leading symptoms of dyspepsia—vomiting, pain, and flatulence—may be misinterpreted by the patient (and his doctor) and be supposed to indicate a primary disorder of the stomach, when in reality the real seat of the disease is somewhere else. It will be sufficient to enumerate some of the chief causes of these symptoms which are liable to be thus misinterpreted.

1. *Vomiting.*—The chief sources of fallacy here are (a) Pregnancy, (b) Uræmia, (c) Chronic intestinal obstruction, (d) Disease of the nervous system, *e.g.*, cerebral tumour, incipient meningitis, the gastric crises of tabes, and hysterical or nervous vomiting, (e) Phthisis. In all of these conditions gastric symptoms, and especially vomiting, may so predominate as to lead to an erroneous diagnosis of dyspepsia.

2. *Pain.*—The pain of gastric disease may be simulated by that due to (a) Gall-stones, (b) Chronic appendicitis, (c) Mucous colitis, (d) Angina pectoris and "abdominal" angina, (e) Pleurisy, (f) Spinal caries, (g) Abdominal aneurysm.

3. *Flatulence.*—The commonest error in this connection is the mistaking of "eructatio nervosa" for flatulent dyspepsia; but flatulence may also be a prominent symptom in cholelithiasis, emphysema, cardiac disease, and angina pectoris, in all of which its significance is easily misinterpreted.

If the possibility of mistake in any of the above directions is present to the mind, it can usually be avoided without much difficulty, but it is important to exclude such conditions at the outset, and to make sure that the symptoms of which the patient complains are really due to some primary disease or disorder of the stomach. Assuming that this has been done, one has next to enquire: Are the symptoms due to organic or to functional disease?

The distinction of organic from functional conditions is sometimes very easy, but at others extremely difficult. In certain cases, indeed, it is only by the process of exclusion, or by watching the results of treatment, that one can feel sure he is dealing with a purely functional disorder. Generally speaking, however, the following symptoms point to organic trouble:—(1) Persistent vomiting, (2) Severe pain, (3) Marked interference with the general health; whereas, conversely, the absence of these is in favour of a functional disorder.

1. Wherever vomiting is a prominent feature in the history, the probability is great that one is dealing with organic disease, for functional disorders either do not produce vomiting at all, or it only occurs as an occasional and inconspicuous feature in their course.

2. Pain, if really severe, is also strongly indicative of organic disease, especially of ulcer. The difficulty here is that patients describe pain so inaccurately, and what is to one a mere ache or discomfort, is spoken of by another as if it were really acute. Usually, however, if the pain be of such severity that the patient has to give up work, lie down, and apply heat to the abdomen, organic disease is present.

3. Decided loss of flesh and strength are also strongly in favour of organic disease, for functional disorders, even when they are of some standing, do not produce these effects, or only do so very gradually.

The chief *organic affections* of the stomach are carcinoma, ulcer, organic dilatation, and gastritis. It would be going too far to consider here the differential diagnosis of these; but having decided which is present, the treatment will be found under the appropriate heading. (See STOMACH, CARCINOMA OF; GASTRIC ULCER, ETC.)

If one decides that the case is functional, as the vast majority of cases of dyspepsia are, one has next to determine, before beginning treatment, what particular variety of functional disorder the patient exhibits. Three forms of classification may be adopted: (1) Physiological, (2) Clinical, (3) Etiological.

1. *Physiological*.—In this classification, cases of functional dyspepsia are arranged according to the particular function or functions affected, thus:—

a. Affections of secretion: (i) excess = hypersecretion and hyperchlorhydria; (ii) defect = achylia and hypochlorhydria.

b. Affections of motility: (i) excess = ? pyloric spasm; (ii) defect = atony or impaired motility.

c. Affections of sensation: Excess = hyperæsthesia or gastralgia.

Any of these may be present alone, or two or more may exist in conjunction.

The above is undoubtedly the most scientific method of making a differential diagnosis in cases of functional dyspepsia, but it has the inconvenience of necessitating the use of test meals.

2. *Clinically* cases may be classified, according to the chief symptoms they exhibit, into various ill-defined groups, e.g., atonic, acid, flatulent, nervous, etc.

3. *Etiological*.—Instead of attempting to distinguish between different forms of functional dyspepsia, one may regard it as an aggregation of symptoms of gastric disorder, excited by different causes, and classify cases according to the particular exciting cause at work. This method is simple and convenient, and is also useful for purposes of treatment. Adopting it, one may say that functional dyspepsia may be induced by: (a) Dietetic causes, e.g., unsuitable food, hasty meals, the abuse of alcohol, tea, etc.; (b) Physical causes, e.g., imperfect chewing, defective teeth, oral sepsis, constipation, over-fatigue, deficient exercise, etc.; (c) Mental causes, e.g., overwork, a studious life, etc.; (d) Emotional causes, e.g., shock, worry, etc.

Any one of the above ways of looking at the subject is useful, the essential point being that a classification of some sort should be adopted. Probably a combination of the first and third methods, which takes into account both the particular disorder which is present and the cause which has brought it about, will lead to the best treatment.

The general principles to be observed, therefore, in the treatment of a case of functional dyspepsia are: (1) To attack the cause, if it can be discovered; (2) To adapt the diet to the impaired functional power of the stomach; (3) To administer such drugs as are calculated to stimulate or correct the particular function or functions which happen to be impaired or disordered.

1. When the *cause* of the dyspepsia is dietetic or physical, its removal is usually easy, and involves such measures as correction of errors in eating and drinking, attention to the hygiene of the mouth and to thorough mastication, the removal of constipation, and the institution of improved general hygiene. The following rules should therefore be impressed upon the patient:—

a. Fresh air is important for dyspeptics. Stuffy and crowded places should be avoided.

b. An effort should be made to obtain regular exercise, preferably in the open air. Riding is the best exercise when obtainable, but brisk walking is better than nothing. Bicycling is not to be recommended. Of indoor exercises, fencing and skipping are the best. Loud reading in a standing position is also of great service.

c. A cold or tepid sponge-bath should be taken in the morning, and a warm bath at least once a week. The bath should be followed by a good rub down with a rough towel.

d. Chill frequently aggravates dyspepsia. A flannel (Jaeger) abdominal belt should therefore be always worn, especially in the winter and spring months.

e. Anything which may cause pressure on the stomach should be avoided, such as tight clothing. Cramped postures are also very harmful, such as stooping over a desk or table. If the occupation entails much writing or reading, the posture should be varied from time to time by standing at a high desk.

f. Attention to the teeth is of the greatest importance, and if they are in any way defective, a dentist should be consulted immediately.

g. Rules of diet should be strictly adhered to. Meals should be eaten in company, and taken at regular intervals. Reading during meals must be avoided. Each meal should be preceded and followed by half an hour's rest, either sitting or reclining.

h. The food should be chewed *very* thoroughly, until each mouthful is reduced to a creamy consistence, before being swallowed.

i. Smoking is best avoided altogether. It is least harmful if indulged in about half an hour after food.

j. Attention to regular action of the bowels is of the first importance, but the use of drastic aperients should be avoided.

If the underlying cause of the dyspepsia is, as often happens, a mental or emotional one, its removal is a much more difficult matter, and may, indeed, be impossible. As most of such patients, however, are neurasthenics, and the dyspepsia is simply a consequence of the nervous state, the article NEURASTHENIA should be consulted for hints as to their management.

2. In the *dietetic treatment* it is important to individualize, and to adapt the diet not only to the patient with due consideration of his likes, dislikes, and idiosyncrasies, but also to the particular disorder of function. Thus, in cases of atonic dyspepsia one has to restrict fluids and the use of bulky, innutritious articles of food; in "acid" cases one has to limit the carbohydrates, and so on. Detailed instructions will be found under the headings devoted to the special forms. In all cases, however, it is important to remember that the following are the most "digestible" articles of food (i.e., those which make least demand upon the secretory and motor powers of the stomach):—

Meats : Mutton, venison, sweetbreads, chicken, tripe, rabbit, grouse, partridge, pheasant.

Fish : Whiting, sole, turbot.

Farinaceous foods : Stale white bread, rusks, plain biscuits, rice, tapioca, sago, arrowroot.

Vegetables : Asparagus, sea-kale, spinach, cauliflower, French beans.

Fruits : Baked apples, the juice of oranges or grapes.

"Made dishes," twice-cooked meats, sauces, pastry, pickles, cheese, sweets, and preserves should be avoided altogether. Meat should be underdone; fish should be boiled or steamed.

In cases of "nervous" dyspepsia (i.e., those in which all the stomach functions are found upon investigation to be normal), and gastropnoia, and in many cases of the "atonic" variety, however—in a word in all dyspepsias associated with a neurasthenic state—it is often necessary to throw dietetic rules to the winds and to feed the patient up, it may be even by means of a Weir-Mitchell course. (See NEURASTHENIA.)

3. In the selection of *drugs* in the treatment of dyspepsia, it is important to avoid all routine and rule-of-thumb procedure, and to compile one's prescription with an eye to the special disorder or disorders of function, whether secretory, motor, or sensory, believed to be present. There is no lack of medicinal agents from which to make a choice, thus :—

a. If *secretion be in excess*, one may give belladonna, bromides, or bismuth

before meals in order to lessen it, or earthy carbonates some time after meals to neutralize it. (See HYPERCHLORHYDRIA.)

b. If *secretion be defective*, one can give bitters before meals to stimulate it, or hydrochloric acid or acidol, with or without pepsin, after meals to supplement or replace it. (See ACHYLIA.)

c. If *motility be defective*, strychnine, bitters, physostigmine, and alcohol are useful as muscle-stimulants, and carminatives may be employed to expel flatus. (See DYSPEPSIA, ATONIC, AND GASTROPTOSIS.)

d. If *hyperæsthesia be present*, there is a large class of sedatives to choose from, e.g., bismuth, bromides, opium, chloroform, hydrocyanic acid, cannabis indica, etc. (See GASTRALGIA.)

The following are some typical prescriptions illustrating the use of drugs in different disorders of function :—

FOR HYPERSECRETION (HYPERCHLORHYDRIA, ACID DYSPEPSIA, ETC.).

R Sodii Bromidi	gr. x	Aquæ Chloroformi	℥ss
Bismuthi Carbonatis	gr. xv		

Before meals.

R Sodii Bicarbonatis		Magnesii Carbonatis Ponderosi	āā
Bismuthi Bicarbonatis			

A small teaspoonful in a little water or milk about two hours after meals.

FOR DEFICIENT SECRETION (HYPOCHYLIA, ACHYLIA, GASTRITIS, ETC.).

R Sodii Bicarbonatis	gr. x	Spiritus Chloroformi	℥x
Tincturæ Nucis Vomice	℥x	Infusum Gentianæ Compositum	
		(N.F.) ad	℥ss

Before meals.

R Acidi Hydrochlorici Diluti		Aquam	ad ℥ss
Glycerini	āā ℥xv		

About twenty minutes after meals.

R Glycerini Pepsini	℥j
---------------------	----

To be taken with the above mixture.

FOR DEFECTIVE MOTILITY (ATONIC DYSPEPSIA, GASTROPTOSIS, ETC.).

R Tincturæ Nucis Vomice	℥xii	Infusum Quassiae (1 per cent)	ad ℥ss
Tincturæ Cardamomi Compositæ	℥ss		

Before each meal.

R Mentholi	gr. ¼	Spiritus Chloroformi	āā ℥j
Spiritus Ammoniae Aromatici			

A teaspoonful as required for flatulence.

FOR HYPERÆSTHESIA (GASTRALGIA).

R Bismuthi Carbonatis		Tincturæ Chloroformi et Morphinae	
Sodii Bicarbonatis	āā gr. xv	(B.P.)	℥v-x
		Aquam Chloroformi	ad ℥ss

In a little water before food.

FOR DEFECTIVE MOTILITY COMBINED WITH HYPERSECRETION OR HYPERÆSTHESIA.

R Bismuthi Carbonatis		Tincturæ Nucis Vomice	℥x
Sodii Bromidi	āā gr. x	Syrupi Zingiberis	℥ss
Acidi Hydrocyanici Diluti	℥iij	Aquam Menthae Piperitæ	ad ℥ss

Before each meal.

In addition to the use of drugs, such remedial agents as massage, electricity, and hydrotherapy are of use in some cases, but the indications for these are pointed out in special articles.

Robert Hutchison.

DYSPEPSIA, ACID.—The treatment of this condition is by no means satisfactory ; it is often difficult or impossible to remove, or at any rate to prevent, the recurrence of the exciting cause : in many cases this condition is undoubtedly due to the presence of an ulcer, either gastric or duodenal, and may call for surgical treatment. Everything possible should be done to improve the general health. Rest and change of air are of value, and such cases derive benefit from a course of treatment at Vichy. So long as the attack lasts the diet must consist chiefly of meat and other albuminous food, with fat and a minimum of starchy food. Patients often do well on Salisbury diet of lightly-cooked minced meat with hot water ; others do better on a strictly vegetarian mode of life. Alkalies with bismuth should be given before each meal.

R. Sodii Bicarbonatis		Mucilaginis Tragacanthæ	℥xv
Bismuthi Carbonatis		Aquæ Menthæ Piperitæ	q.s. ad 3j
Magnesi Carbonatis	āā gr x		

Two tablespoonfuls before each meal.

According to Pavlov, olive oil when introduced into the stomach before meals diminishes and delays the secretion of gastric juice, but the quantity of oil used was 100 c.c., that is, 3½ oz. It has been used in much smaller doses, from 1 dr. to ½ oz., to check hypersecretion, not only in simple neuroses, but where it has been associated with gastric ulcer and other organic conditions. The good results which have been recorded suggest the desirability of giving a further trial to this treatment.

R. Olei Olivæ	3j	Aquæ Aurantii Florum	q.s. ad 3j
Pulveris Tragacanthæ Co. (B.P.)	gr xx		

Two tablespoonfuls before each meal.

The use of the stomach tube is indicated in those cases where relief cannot be obtained in any other way, as by its means life may be made tolerable.

Some authors speak highly of belladonna and its alkaloid atropine as possessing the power to diminish the secretion of gastric juice, but in practice they are not trustworthy. Eumydrine (methyl-atropine-nitrate) is claimed to possess a more powerful action than atropine, the dose being one drop of a 1 per cent solution. Hydrogen peroxide is also given in doses of half a drachm to a drachm. Bromide of potassium, too, is theoretically indicated, but is not of much service. (See also GOUT.)

Robert Saundby.

DYSPEPSIA, ANACID.—(See ACHYLIA.)

DYSPEPSIA, ATONIC.—The rational treatment of this very common condition by removal of the cause is unhappily sometimes beyond our power, but where possible we should prescribe rest, such as can often only be obtained by leaving home. More obstinate conditions call for a Weir-Mitchell course, which should not be for less than three months. It is the type of dyspepsia met with so very frequently among women of the poorer classes, and is largely dependent upon fatigue, faulty feeding, and worry, and affords an excellent example of a vicious circle. It may be complicated to some extent by gastritis, but the latter is not the real malady. The diet should be an abundance of simple digestible food suited to the patient's taste. These are eminently unsuitable cases for strict regimen ; they are apt to starve themselves, to follow every quack system, and to eat every patent food ; but it may be desirable to warn them against indigestible food, and if gastritis be present, treatment suitable for that condition must be ordered.

The most useful medicine after any gastritis has been allayed is the following

acid mixture, together with a vegetable aperient, of which cascara is, perhaps, the most generally successful :—

R	Acidi Nitrohydrochloridi Diluti	℥x	Succi Taraxaci (B.P.)	℥j
	Tincturæ Nucis Vomiceæ	℥xxv	Aquæ	q.s. ad ℥j

Two tablespoonfuls after each meal.

Robert Saundby.

DYSPEPSIA IN CHILDHOOD.—Disorders of digestion in infancy are considered under the headings, of COLIC, VOMITING, and DIARRHŒA, but in this article one has to deal with the characteristic digestive disorder of later childhood. The chief symptoms of this affection are : wasting, capricious appetite, flatulence, constipation, and vague abdominal pains ; and it is frequently complicated by the presence of adenoids and by functional disorders of the nervous system, such as headaches, night-terrors, and enuresis. Such cases are apt to be misunderstood, and the patients are often believed (erroneously) to be suffering from tuberculosis, but the symptoms are probably really due to a catarrhal condition of the alimentary canal. They have been described by Dr. Eustace Smith under the title “Mucous Disease,” from the fact that mucus is often passed in considerable quantities with the motions.

The usual mistake made in the treatment of these patients is to attempt to “feed them up” by giving milk freely and by administering cod-liver oil and iron (usually in the form of “chemical food”). What they really need is (1) Regulation of the diet ; (2) Change of air ; and (3) The use of alkaline bitter tonics ; and (4) Aperients.

1. The most important part of the *dietetic treatment* is to reduce the amount of starches and sugar in the food. The following articles should be avoided : Ordinary bread, porridge, farinaceous puddings, sweets, jams, raw fruit, vegetables (except a little cauliflower, spinach, or *mashed* potato), and pastry ; and the diet should consist of stale white bread or crisp toast, rusks, malted foods, jellies, custards, a little stewed fruit, baked apple or fruit juice, lightly cooked eggs, and underdone meats. Milk is not usually well borne, and not more than a pint should be given per day ; it is best diluted with water or lime-water ; cocoatina may be substituted at breakfast or tea. No food should be given between the regular meals.

2. *Change of air* is of the greatest help, especially when the appetite is poor. The seaside suits some children very well, the east coast being best in summer and the south coast in winter ; but others do better at hilly inland resorts. It is often advisable to send dyspeptic children away for a short change three or four times a year, if it can be managed.

3. As regards *drugs*, alkaline bitter tonics usually give good results (e.g., sodium bicarbonate 3 to 5 gr., tincture nux vomica 2 to 6 min., spirit of chloroform 7 min., compound infusion of gentian (N.F.) 1 to 2 dr., before each meal). If the tongue be furred and the breath offensive, a mixture of rhubarb and soda may be given for a week or two at first (e.g., rhubarb powder 1 gr., sodium bicarbonate 3 gr., tincture of nux vomica 5 min., syrup of ginger 10 min., peppermint water to 2 dr., after each meal for a child of five). When the tongue has become clean, iron may sometimes be given with advantage, but it is usually best to combine it with an aperient (e.g., 1 dr. each of iron wine and compound decoction of aloes (B.P.) ; or sulphate of iron $\frac{1}{2}$ to 1 gr., magnesium sulphate 5 to 10 gr., dilute sulphuric acid 1 to 2 min., syrup of ginger 3 to 5 min., add peppermint water 1 to 2 dr., after each meal). A teaspoonful of a good malt extract may be given after meals, both as a digestive and as a food.

4. *Aperients* are necessary in the great majority of cases. Of these none is better than a combination of rhubarb and grey powder (rhubarb powder 3 to 5 gr. or more, with grey powder, $\frac{1}{2}$ to 1 gr.), but elixirs of cascara, senna, etc., are also useful. (See CONSTIPATION IN CHILDREN.)

In order to avoid relapses, attention should be given to general hygienic measures. Chill especially should be guarded against by suitable clothing, and excitement and over-fatigue, whether mental or physical, avoided. It may therefore be necessary to curtail lessons and to see that more time is spent in the open air. A mid-day rest in bed or on a couch is often of help where the child shows signs of exhaustion.

Robert Hutchison.

DYSPNŒA.—(See ASTHMA ; BRONCHITIS ; CROUP ; HEART ; ETC.)

EAR, AFFECTIONS OF.

I.—AURICLE.

Carcinoma demands early and wide removal of the affected parts and the neighbouring glands. The upper half of the auricle is the usual site. An artificial auricle can afterwards be worn. In inoperable cases radium should be used.

Cysts.—*Sebaceous* cysts, usually found in the lobule and back of the auricle, require dissecting out. Occasionally *serous* cysts form spontaneously in the upper and outer part between the perichondrium and the cartilage; these should be opened and drained. *Dermoid* cysts are occasionally found in front of or behind the auricle, and should be dissected out.

Eczema, Acute and Chronic.

Acute Eczema yields to simple treatment. The parts should be kept covered with boracic acid or oxide of zinc ointment, smeared thinly on butter muslin carefully applied to the inequalities of the ear, and kept in position by absorbent wool and bandage. A 10 per cent watery solution of ichthyol gives good results. For cleaning, parolein or oatmeal and water should replace soap. Recurrence is not uncommon, and attention must be paid to the general health.

Chronic Eczema.—The crusts should be removed with a greasy poultice or parolein, and then either of the following applications should be applied three or four times a day :—

R Unguenti Hydrargyri Nitratis	3j	Paroleini	q.s. ad 3j
R Liquoris Carbonis Detergentis	℥v	Zinci Oxidi	3j
Hydrargyri Ammoniati	3ss	Vaselini	q.s. ad 3j

Painting the parts with nitrate of silver, gr. ij to the 3j, is sometimes of great benefit.

The following application is often valuable :—

R Liquoris Plumbi Subacetatis	℥ xv	Glycerini	3ss
Calaminæ	gr xxv	Aquam Rosæ	ad 3ij

The bottle to be well shaken before use.

To prevent scratching it may be necessary to tie a child's hands or to cover them with lint. The general health will usually require attention. Arsenic internally is sometimes of value.

Erysipelas is occasionally associated with chronic eczema of the meatus. Ichthyol in water, 25 per cent, should be painted on the parts twice a day, with protection by means of absorbent wool and a bandage, together with the usual ordinary general treatment. Chronic eczema of the meatus, if present, should be treated to prevent recurrences.

Fibroma.—This tumour occurs in the lobule in connection with the holes made for the wearing of ear-rings. The tumour should be removed by means of a V-shaped incision, the opening of the V being at the edge of the lobule.

Frost-Bite.—In recent cases the ear should be rubbed with snow or cold water until the circulation returns. Any ulcers which may subsequently form require boracic acid ointment.

Hæmatoma.—This is an effusion of blood, usually due to injury, between the perichondrium and the cartilage, and if allowed to run its course, a shrunken, deformed auricle results. The blood should be evacuated by a free incision under antiseptic precautions, and a double cyanide gauze dressing, packed carefully into all the inequalities of the auricle, should be kept on with wool and bandage. The cleft between the auricle and the head should be filled with the gauze.

Herpes.—Boracic acid ointment, with absorbent wool and bandage, is all that is necessary. Herpes of the auricle may be associated with neuritis of the auditory and facial nerves.

Injury.—The auricle may be severely torn or cut. The parts should always be purified carefully and replaced in position with a few stitches, however impossible the chances of healing may appear, even if the whole organ has been removed.

Lupus is rarely primary in the auricle. The treatment is the same as in other parts of the body, but sometimes the disease in this position is more easily treated by excision.

Malformation.—Small fistulæ in front of the ear, leading towards the meatus, may be dissected out if they are the site of recurring inflammation.

If the auricle is rudimentary and no passage exists, operations undertaken with the view of forming an auricle or of making a meatus are contra-indicated. An artificial auricle should be worn, the rudimentary organ being used for its attachment. Supernumerary auricles can be dissected out.

If the auricle is very large, it can be reduced in size by a carefully planned operation; or if it projects in an unsightly manner, an elliptical portion of skin is removed from the back of the auricle and from over the mastoid process, and the edges of the resulting wound are brought together by stitches. It may be necessary to remove part of the cartilage.

Papilloma.—Occasionally ordinary warts are seen on the auricle, but do not demand special treatment. Single papillomatous growths should always be excised, especially in later life, as they may be the starting-point of epithelioma.

Perichondritis.—If the perichondrium becomes infected as a result of injury, operative or otherwise, the cartilage sloughs away and a shrunken auricle results. Free incisions should be made, and hot boracic fomentations constantly applied.

Syphilis.—The auricle is very rarely the site of a primary sore, but of course shares in the rashes in the later stage. Occasionally a tertiary ulcer is seen, and may be mistaken for carcinoma. Rarely, small tertiary ulcers are found on the edge of the auricle. Ordinary treatment always suffices.

II.—EXTERNAL AUDITORY MEATUS.

Aspergillus or Otomycosis.—This is only occasionally seen in England. Frequent re-accumulation of masses of epithelium with dark spots on it, associated with irritation and swelling of the meatal walls, should arouse suspicion. The microscope will put the diagnosis beyond doubt. In treating it, the object is to destroy the fungus. The meatus should be syringed with warm 1-500 perchloride of mercury night and morning for four days, and the meatus filled afterwards with hydrarg. perchlor. 1 gr., sp. vini rect. 1 oz., the head being placed on one side and the solution allowed to remain in for a quarter of an hour.

If much inflammation of the parts is present, it should first be treated by hot boracic acid lotion syringing and hot fomentation.

Atresia.—If congenital, treatment is most unsatisfactory, unless it can be definitely determined that the middle and internal ears are healthy and the atresia is simply due to a mere partition of soft parts. The partition should be cut away and the passage kept open by means of leaden tubes until the raw surfaces have skinned over. It may be necessary, however, to turn the auricle forwards, remove the partition, and skin-graft.

Atresia may result from injury or inflammation, and the same treatment will be necessary.

Stenosis occurs as a result of chronic eczema, inflammation, injury, or bony growths. As long as a permanent opening, however small, remains, it will be found that it is sufficient for hearing, and nothing need be done after the local trouble is cured.

Carcinoma.—This may start in the cartilaginous part of the meatus after long-continued eczema, or at the site of a wart; or the passage may be secondarily involved from neighbouring parts. Free removal and the application of radium are the methods of treatment. It will be found that even if complete removal is impossible, the treatment will relieve the intolerable pain.

Caries.—Death of part of the bony meatus may occur as the result of a localized abscess, but it is usually secondary to extension from the middle-ear tract.

If due to the former, free curetting and the removal of the diseased bone through the meatus will effect a cure. It may be necessary, however, to turn the auricle forward to obtain enough room.

Cerumen.—The mass will, as a rule, be easily removed by syringing. Before syringing the ear, an examination should be made to make sure that it is required. Great harm may be done by needless syringing.

The syringe should be of one-ounce capacity, with a projecting rim for the fingers, and should have a nozzle with a thin but smooth point. Care should be taken that the syringe is pure, either by immersion in and filling with carbolic solution 1-20, or by boiling. Not uncommonly one syringe is made to do duty for all ears, septic or not, without any purification, and occasionally great harm results. The water should be previously boiled and be used warm. A good guide is to have the water of such a temperature that it is pleasantly hot when applied to the back of the hand.

The patient should be seated opposite a window, with the light falling on the ear to be syringed. The auricle is then pulled—downwards in an infant, downwards and backwards in a child, and upwards and backwards in an adult—in order to straighten the passage.

The syringe having been filled, and all air having been expelled, the nozzle is placed just inside the meatus, and the water is projected along the posterior wall in a slightly jerky manner, the process being repeated until the mass is expelled.

The ear should then be emptied of water by turning the head on one side; and it should then be examined to make sure that the passage is clear, and a light plug of wool introduced and worn for a few hours.

If there is difficulty in removal, or if it is obviously very hard, the mass may be softened by filling the passage, while the head is placed on one side, with the following solution, used warm, and allowing it to stay in for a quarter of an hour three times a day :—

R. Sodii Bicarbonatis
Glycerini

gr xv | Aquæ Destillatæ

āā ʒj

Parolein or peroxide of hydrogen is also useful. When ordering the instillation, the patient should be warned that it may make the hearing temporarily worse.

If the passage is swollen and tender, hot fomentation, together with the instillation, should be used before syringing. Occasionally the passage is filled with layers of desquamated epithelium mixed with cerumen (*Keratosis obturans*), and the mass is often very difficult to remove, especially as the walls of the passage are usually very tender. Syringing after frequent softening may be efficacious, but it is often necessary to separate the mass gently from the wall at one point with a small silver loop, and then to seize the separated part with ear forceps and gently pull the whole mass out. In very nervous patients an anæsthetic may be necessary. After removal of the epithelial plugs an enlargement of the floor of the bony meatus is occasionally found. The ear should be examined and cleaned about once in two months, to prevent discomfort and deafness.

Diphtheria.—This is usually due to spread of the infection from the middle ear, but it may be purely local. The local treatment consists in syringing the ear four times a day with a saturated solution of toluol, the application of hot fomentation, and the usual serum injection.

Eczema localized to the meatus is very often due to the bad habit of picking the ear with the nail, or with the pernicious instruments sold for cleaning the ear. As the itching is often nearly intolerable, great self-control is necessary to abstain from scratching the parts. Brisk rubbing in front and behind the ear, well away from the meatus, with the first two fingers, will alleviate the extreme irritation. The passage should be gently painted two or three times a day with the following preparation:—

R Unguenti Hydrargyri Nitratis

ʒj | Paroleini

q.s. ad. ʒj

A little being poured out, after shaking, on to the bottom of an inverted tumbler, is lightly applied with a camel's-hair brush, which should be thoroughly cleaned and dried after each application. The patient should be warned not to rub the parts with the hard part of the brush, as the temptation to do so is very great. If the meatus becomes occupied by offensive discharge, and there is thickening of the skin, perhydrol (vols. 10) instillations for five minutes, night and morning, followed by syringing with warm boiled water or sterile salt solution, and the subsequent application of the calamine lotion (B.P.C.) (see CHRONIC ECZEMA OF AURICLE), will be found of great value; the number of times the treatment is applied being gradually lessened as improvement takes place.

At night a broad ring pad may be worn round the ear, or the pillow may be curved round in such a way as to prevent rubbing. The secretion tends to collect in the meatus, and often becomes very offensive; syringing with boiled boracic acid lotion or sterile salt solution once or twice a day, before applying the mercurial application, is then necessary.

Should the passage become extremely contracted, a thin wick of wool soaked in the application should be worn all night, and gradually increased in thickness as the passage opens. General anti-gout treatment is useful, and also arsenic.

The eczema may be due to the irritation of a septic middle-ear discharge.

Endothelioma.—This rare tumour of the meatus requires thorough removal of the whole cartilaginous meatus, with subsequent skin grafting to keep the passage open. Radium should also be used. As most of the pinna is left, the resulting deformity is slight.

Epithelial Plugs, or Keratosis Obturans.—(See CERUMEN, *supra*.)

Erysipelas.—Recurring attacks often begin in the meatus in cases of eczema. The disease is likely to spread beyond the auricle on to the head, but the deep meatus and the middle ear are rarely if ever affected. Ichthyol during the attack, and cure of the chronic eczema, are the lines of treatment.

Exostosis and Hyperostosis.—Bony growths in the meatus take three forms:

(1) Multiple, sessile, ivory, in the deep meatus ; (2) General thickening of the bony meatus, or hyperostosis ; (3) Single pedunculated.

1. The *Multiple Growths* are usually three in number. They very rarely cause symptoms, but the chink between them is readily blocked with cerumen. They hardly ever require removal, but they may cause retention of pus in suppuration of the middle ear, and will then have to be dealt with. They may be removed through the meatus with a small trephine (Pritchard's), worked by a dental engine or electric motor, or the auricle may be turned forwards and the growths chiselled off.

2. *Hyperostosis* also very rarely requires surgical interference. The excess of bone may be removed through the meatus with a chisel and hammer, or by a burr worked by a motor.

3. The *Single Pedunculated* variety is rarely seen. It grows close to the orifice of the meatus, and may quite occlude the passage, causing deafness. The growths are easily broken off with dental stump forceps.

Foreign Bodies.—Unless the foreign body is a living insect, its presence in the meatus rarely causes much discomfort or danger. The danger lies in roughly attempting to remove it.

In all cases the presence of the foreign body must be ascertained by means of a good light reflected into the ear through a speculum from a head mirror. In children an anæsthetic will sometimes be necessary. If a living insect is present, the head should be placed on one side and the meatus filled with paroline or chloroform vapour ; the insect will either come out of its own accord or will be killed, when it is easily removed by syringing.

Other foreign bodies should be *syringed* out, and unless the operator is skilled in aural work, nothing further should be attempted. Rough efforts at removal may result in rupture of the membrane, removal of the ossicles, facial paralysis, meningitis, or cerebral abscess. The syringing should be done under aseptic conditions (see CERUMEN, *supra*). If there is a chink between the foreign body and the meatal wall, the stream should be directed through it. If the foreign body is heavy, the ear may be turned downwards and the syringing done from below.

If the meatus is swollen external to the foreign body, removal should not be attempted—unless symptoms indicating urgency are present—until the inflammation has been reduced by hot fomentation. If syringing is not efficacious, instrumental removal will be necessary under strict antiseptic precautions. The meatus and auricle should be purified—the meatus by instillation for twenty minutes of 1–20 carbolic acid solution and subsequent syringing with 1–2000 solution of perchloride of mercury. The auricle is purified in the ordinary way, and all instruments should be boiled and placed in 1–20 carbolic acid. The parts, if they are dry, may be rapidly purified by the application of iodine in alcohol, 2½ per cent. There is sometimes great scope for ingenuity in removing a foreign body.

If removal through the meatus is impossible, more room can be obtained by turning the auricle forward and removing enough of the posterior and superior walls of the bony meatus with a chisel and hammer.

If dangerous symptoms are present, it will be necessary to lay the middle-ear tract thoroughly open, and to deal with any intracranial trouble which may have resulted.

Furunculosis or Boil.—These are always situated in the cartilaginous meatus, and the quickest way of dealing with them is to make a free and deep incision through the inflamed tissues, under gas anæsthesia, with a narrow, probe-pointed knife. Even if pus has not yet formed, the relief will be great. After the incision, hot fomentation and frequent syringing with hot 1–2000 solution of perchloride of mercury are necessary. If incision is impossible or refused, a poultice, followed

by hot fomentation, should be applied until the boil bursts. Morphia may be necessary to relieve the pain and to procure sleep. Recurrence is often seen, and to prevent this it is necessary thoroughly to purify the cartilaginous portion of the meatus after the inflammation has subsided. This should be done by instillation of 1-20 carbolic acid for twenty minutes, followed by a light gauze plug soaking with 1-2000 perchloride of mercury, every day for three days. The general health will require attention. If recurrence takes place in spite of thorough purification and attention to the general health, vaccine treatment will be found valuable.

Boils are sometimes associated with chronic eczema and with suppuration of the middle ear.

Herpes.—Herpetic eruptions may occur in the meatus or on the membrana tympani. If on the membrane, it is important not to mistake the condition for acute middle-ear inflammation. Hot fomentations and morphia internally will relieve the pain before the vesicles have burst; after rupture has occurred, boracic acid powder should be insufflated. General tonic treatment and rest from worry are indicated. Herpes of the auricle and neck is sometimes associated with facial paralysis, giddiness, and internal-ear deafness. Recovery usually takes place with rest and counter-irritation. It is well, however, to have a Wassermann test made.

General or Diffuse Inflammation.—Any cause, such as discharge from the middle ear, aspergillus, or cerumen, should be removed. Hot fomentations and hot boiled boracic syringing should be used, and any granulations which form should be lightly touched with solid nitrate of silver fused on the end of a silver probe.

Papilloma.—Single papillomatous growths should always be widely removed, as they may be the starting-point of epithelioma.

Polypi.—As a rule polypi in the meatus are merely exuberant granulation tissue coming from a septic middle-ear tract. Their treatment is described under middle-ear suppuration. When they occur as a result of inflammation of the soft tissue of the meatus, they should be lightly touched with nitrate of silver, and the ear syringed with boiled boracic lotion or 1-4000 perchloride of mercury night and morning. If the bone is carious, the parts should be thoroughly curetted under an anæsthetic. Carcinoma and sarcoma appear as a polypus or a mass of granulations; the very free bleeding and the extreme pain produced by gentle manipulation with a probe will arouse suspicion.

Sarcoma is rare as a primary growth of the meatus, which is more often invaded from a tumour in neighbouring parts. Free removal after turning the auricle forward, and the application of radium, are the methods of treatment.

III.—MIDDLE EAR.

Carcinoma.—Treatment is palliative—a complete removal is impossible. Free opening of the middle ear, antrum, and mastoid process, with removal of as much of the disease as is possible, is often of value in relieving pain. Radium should be used.

Catarrh, Acute and Chronic.—Catarrh of the middle ear results from a catarrh of the nasopharynx spreading up the Eustachian tube.

Acute Catarrh.—In the acute stages, rest, purging, light diet, with complete abstinence from tobacco and alcohol, with hot inhalation of benzoin four times a day for five minutes, and gentle inflation with Politzer's bag twice a day, are all that is necessary. In the subacute stage, chloride of ammonium vapour produced by Rogers' inhaler is valuable. The vapour is drawn into the mouth from the mouthpiece, and then blown through the nose, for ten minutes night and morning,

and twice at each sitting the vapour should be introduced into the middle-ear tract by blowing down the tightly closed nose when the mouth and nose are full of the vapour. If it is desired to inflate one ear more than the other, the patient should place the head on one side, with the affected ear uppermost and the other ear blocked with the finger. A warm sterile astringent and alkaline nasal solution, or glycothymoline solution, should be poured into the nose after the inhaler has been used. Politzer's bag (see EUSTACHIAN OBSTRUCTION, *infra*) will be required once a day, with increasing intervals as the hearing improves. If the blockage is very great, the Eustachian catheter (see EUSTACHIAN OBSTRUCTION) may be necessary after the acute stage is over. Injection through the catheter of 10 drops of warm parolein, or a warm sterile solution of pot. iod. 10 gr. to the ounce, or sod. bicarb. 5 gr. to the ounce, is sometimes of value, especially if the catarrhal fluid is very sticky in character.

Change of air, especially to the seaside, is of the greatest value. Tonics should also be given. In very obstinate cases it is sometimes necessary to evacuate the contents of the middle-ear tract by making an incision in the posterior and inferior segments of the membrane, and subsequently removing the catarrhal fluid by means of Politzer's bag, or by sucking it out with Siegle's exhausting speculum, or both methods may be employed.

Any unhealthy condition of the nose and nasopharynx will often require dealing with before a complete cure is obtained, and also to prevent recurrences. Adenoids will often be found.

Chronic Catarrh.—If the condition has become chronic, the nose, nasopharynx, and throat should be thoroughly examined and made in as healthy a condition as possible; the tube should be kept open by regular inflation with Politzer's bag or the Eustachian catheter; the membrane and ossicles be kept supple by gentle massage with Delstanche's masseur for one minute night and morning, and chloride of ammonium vapour used off and on in the manner previously described.

A high and dry climate will be beneficial, and the diet should be light, with only one meat meal a day; plenty of fluid should be taken. Alcohol and tobacco should be absolutely stopped. The whole body should be rubbed briskly with a rough towel night and morning, and a Turkish bath may be taken once a month. Occasionally the hearing in these cases is improved by making a hole in the membrane. If the patient states that he hears better in a noise, treatment will be of little value.

Eustachian Obstruction.—The cause in the nasopharynx should be searched for and treated. It may be due to catarrh, often associated with adenoids, new growth, or cicatricial contraction.

The tube should be opened and kept patent by various methods, and the one employed will depend on the cause and persistency of the obstruction. After the subsidence of acute inflammation at the mouth of the tube, or the removal of a new growth from the nasopharynx, the mere act of swallowing will often do all that is necessary. If the closure persists, Valsalva's method of auto-inflation may be efficacious. The nose is tightly held while the patient blows strongly down it and at the same time makes an effort at swallowing. Inflation with Politzer's bag is often necessary, and may have to be repeated daily until the hearing returns. An eight-ounce bag, to the nozzle of which a nosepiece (Pritchard's) is connected by means of a short piece of rubber tubing, is the best. The patient having taken a sip of water, the end of the nosepiece is placed just inside the nose, past the vestibule, which is higher than the floor of the nose, with the opening pointing down the inferior meatus; the nostrils are then closed round the nosepiece with the finger and thumb of the left hand, and the patient is directed to swallow. When the larynx is seen to move upwards—and it is a good plan to place the patient's head sideways to the

surgeon in order to see this—the bag is sharply squeezed with the right hand, taking care that the bag is not jerked upwards, for if it is the tube becomes kinked and no air passes. The grasp of the bag should not be relaxed until the nosepiece has been withdrawn and cleaned, for if the bag is allowed to expand with the nozzle in the nose, mucus is sucked in. On efficient inflation the patient will experience an explosion in the ear, and the hearing will at once be greatly improved. The surgeon can hear the air enter the middle ear if an auscultation tube connecting the patient's ear with that of the surgeon is used. Instead of swallowing water, the soft palate may be made to shut off the nasopharynx from the pharynx by blowing out the cheeks or by saying "hic."

If there is difficulty in opening the tubes with the bag, a few drops of chloroform may be poured into the bag and allowed to evaporate before inflation.

If it is desired to inflate one ear only, the head should be placed on one side, with the affected ear uppermost and the other blocked with the finger. The nosepiece of the bag should be carefully purified after each patient.

For Eustachian catheterization, a medium-sized short silver catheter, with a ring on the butt corresponding to the point, is the best. Before use it should be boiled, and air should be blown through, to make sure that the instrument is clean and clear. The nose should be examined for anything, such as deviation of spurs from the septum, likely to prevent or hinder the passage of the instrument. If it is impossible to pass the catheter down one side of the nose, both ears may be catheterized through the clear one, a right-angle bend being made in the instrument to reach the tube on the obstructed side. At the first sitting, or if the patient is nervous, a 2 per cent solution of cocaine should be previously sprayed along the inferior meatus. The surgeon, seated opposite the patient, first places the ends of the auscultation tube in his own and the patient's ear. With the last three fingers of the left hand resting on the bridge of the nose, the tip of the nose is tilted up with the left thumb, and the point of the catheter is introduced into the lower part of the nostril, with its opening pointing backwards and the bend forwards. After it is passed through the vestibule, which is higher than the floor of the nose, the surgeon's end of the instrument is raised so that the main part is horizontal and the point rests on the floor of the nose. The instrument is then gently passed straight backwards, being rotated round any obstruction from the septum, until the posterior nasopharyngeal wall is reached. The feeling closely resembles that experienced on pressing the point of the catheter against the palm of the hand.

At this point the ring on the catheter will point downwards; it is then turned inwards and upwards, so that the ring points horizontally away from the ear to be catheterized; the catheter is gently pulled forwards until the posterior edge of the septum is felt, when the point is rotated downwards, outwards, and upwards, until the ring points to the outer canthus of the eye and the point is lodged in the mouth of the tube. The catheter is fixed in this position by the thumb and first finger of the left hand, and the nozzle of the inflating bag fitted into it. On inflation, the air can be heard to pass through the Eustachian tube and reach the middle ear; if catarrhal fluid is present in the tube or middle ear, bubbling will be heard. The blowing should continue until about six clear inflations have been heard; it may, however, take several sittings before the air can be heard clearly to enter the middle ear.

If it is desired to introduce fluid into the middle ear, the catheter is passed, and inflation made to ascertain that the instrument is in the mouth of the tube; the inflating bag is then detached, and by means of a pipette or syringe the warmed solution is injected into the catheter and blown into the middle ear with the inflating bag. Vapours may also be introduced either by a special apparatus or by filling the inflating bag.

Foreign Bodies.—These are not common in the middle ear. In most instances they have been pushed through the membrane by rough attempts made to remove them from the meatus. They demand prompt removal. If aseptic syringing is not successful, the foreign body will have to be removed instrumentally through the meatus under an anæsthetic and with strict antiseptic precautions. It may be necessary to enlarge the opening in the membrane, or even to turn the ear forwards and to chisel away the posterior and superior bony meatal walls to give more room. If sufficient room is not then obtained, the middle-ear tract must be thoroughly opened, as in the complete post-aural operation; in fact, sepsis may compel the surgeon to adopt this radical measure.

Inflammation, Acute and Chronic.—

Acute Inflammation.—In the early stages, when there are merely injection of the malleal vessels and general redness without bulging of the membrane, the inflammation can sometimes be cut short.

The first thing is to put the patient to bed, purify the meatus by instillation of warm 1–20 carbolic for a quarter of an hour, and introduce a light plug of double cyanide gauze wrung out in 1–2000 perchloride of mercury; the auricle, also filled and covered with the gauze, is kept in position by wool and bandage.

Purification and plugging serve several purposes: functional rest is obtained; the parts are ready if an incision has to be made in the membrane, and if an abscess rapidly forms and bursts through the membrane, it does so into an antiseptic dressing. Hot fomentations are applied over the ear without disturbing the gauze. Blistering or counter-irritation over the mastoid should not be used, for their effects may subsequently mask mastoid signs. As the inflammation has spread up the tube from the nasopharynx in the great majority of cases, warm benzoin inhalation through the mouth and nose every two hours should be ordered. A gentle inflation with Politzer's bag will open the tube and relieve the pain. Morphia should be given if the pain is great and preventing sleep. If the pain is not relieved in six or eight hours, it will mean that the inflammation is not cut short, and that it will be necessary to open the membrane. On looking at the ear it will be found that the redness has increased, and that there is bulging of the membrane, usually in the posterior segment. Under gas anæsthesia the membrane is opened by means of a fine sharp-pointed knife. The incision should start from behind the short process of the malleus, and pass right down through the posterior segment of the membrane. If the bulging is in Shrapnell's membrane it should be included in the incision. The bleeding will be fairly free. The blood and evacuated material should then be gently wiped out with gauze mops, a light plug again introduced, and the outside dressing and fomentation reapplied. The contents of the middle ear may be serous or mucopurulent. The relief to the patient will soon be obvious. The dressings should be changed about every six hours, the frequency depending on the amount of discharge. It may be found that the discharge is quite slight, and rapidly ceases without any syringing, or it may become very profuse, necessitating frequent dressing and the clearing of the meatus by gentle syringing with warm boiled boracic lotion or sterile salt solution; in these circumstances it is wise to omit the meatal gauze, and have an outer dressing only. Strong antiseptic solutions should be avoided.

When the pain is gone, the fomentation should be left off and a daily gentle inflation made with Politzer's bag. As the discharge lessens, the interval between the dressings is gradually lengthened.

After the attack is over, and the patient has regained his health by change of air and tonics, search should be made for any predisposing cause, especially for adenoids. During the attack the patient should be carefully watched for any sign of extension to the antrum or mastoid process, and for labyrinthine and intracranial complications.

In young children, before the mastoid cells have formed, pus in the antrum, which is part of the middle ear, will perforate high up behind the ear. In dealing with such a case the ear is turned forwards, and only the outer wall of the antrum need be removed to secure good drainage. The middle ear proper should not be touched. The wound being lightly plugged will heal up from the bottom; the discharge from the meatus will quickly subside, and perfect hearing will result.

Fig. 23.—Right Temporal Bone of a male, aged 18 years, sectioned to show mastoid cells well developed.

If the mastoid cells, which always communicate with the antrum, have formed, the external signs will be lower down; sometimes these are very vague, but the discharge remaining profuse and mucopurulent, with pain and slight rise of temperature at night after the trouble has lasted a few weeks, will warrant operation. A most important sign is bulging of the postero-superior deep meatal wall close to the membrane; this sign alone shows that there is pus to be let out, and operation should be undertaken at once. Occasionally, and especially in influenzal cases, the course is extremely rapid, and the mastoid operation may have to be undertaken within a few days of the onset.

In operating when the mastoid cells (*Fig. 23*) are involved, the outer bony wall only should at first be removed. The inner wall of the bony wound should not be touched until the cavity has been cleared of blood and pus and it can be thoroughly inspected by means of reflected light from a head mirror or a head light, for the lateral sinus in its varying positions is frequently exposed by the disease, and sometimes the facial nerve, in the descending part of its course, lies naked at the bottom and front part of the cavity (*Figs. 24, 25*). All the affected cells must be exposed and their partitions removed to lay them open into the main wound. The ramification of the cells is sometimes very extensive. Care should be taken that the opening from the lower part of the antrum into the cavity is made free; the outer wall of the antrum

Fig. 24.—Right Adult Temporal Bone. The mastoid cells have been removed to show the lateral sinus.

need not be touched, nor should the middle ear proper. Healing takes place from the bottom, and the hearing result will be perfect.

The directions which pus may take are very numerous, and depend to a great degree on the anatomical condition. The pus may perforate into the meatus from the antrum or from the mastoid cells. It may get into the neck under the deep fascia through the inner aspect of the mastoid process (Bezold's perforation), or through the digastric or occipital grooves, and it may run down the neck as low as the clavicle, or push into the pharynx or soft palate.

Not infrequently the mastoid cells are absent all through life, and as the outer wall of the antrum in these circumstances is frequently composed of bone of ivory density, and may be three-quarters of an inch thick, an empyema of the antrum may present no external signs; but the discharge will continue to be profuse, there will be some pain and temperature, and the sagging of the postero-superior deep meatal wall will be seen. In this condition the opening in the bone should commence high up behind the ear in Macewen's triangle, which is a good guide to the antrum in the great majority of cases. In the illustration (*Fig. 26*) the triangle is marked out; the oval outline shows the site at which the mastoid cells should be opened.

Fig. 25.—Right Adult Temporal Bone sectioned, and showing diploëtic infantile type of bone. Descending part of facial nerve marked in ink.

Intracranial complications of every variety may occur as a result of acute inflammation of the middle ear.

In all cases of mastoid operation for acute empyema, the middle ear must not be touched. Pus should be tracked wherever it may run, and the cavities thoroughly opened.

Chronic Inflammation.—Chronic discharge from the middle ear is only a sign of disease, and results most frequently from an acute inflammation involving the antrum in bones which are devoid of mastoid cells and which have a dense outer antral wall and a dense layer of bone between the antrum and the diploëtic mastoid (diploëtic infantile type). (*Fig. 25*). The original infection is nearly always due to scarlet fever or measles. The exact local conditions must as far as possible be ascertained: the nature of the discharge; the site and extent of perforation of the membrane; the condition of the mucous membrane on the inner middle-ear wall; the state of the ossicles; the presence or absence of polypus, granulations, cholesteatoma, and caries of the walls of the middle ear and meatus; and as to whether pus can be drawn from the antrum by means of Peter's speculum after drying and cleaning of the middle ear. Signs of extension to the labyrinth must be looked for, and intracranial complications should

be excluded ; these are meningitis, cerebral or cerebellar abscess, and thrombosis of the lateral sinus. An *x*-ray photograph will show the presence or absence of mastoid cells.

The nose, nasopharynx, and pharynx should be examined, and anything unhealthy, especially adenoids, should be removed. The general health should be carefully investigated. In cases of simple, uncomplicated perforation, the ear should be syringed night and morning with warm boiled boracic acid solution, half a pint being used at each sitting. It is best for a previously instructed person to syringe the ear in the same manner as in cases of cerumen. An ounce glass syringe, which should be kept aseptic either by boiling or by immersion in and filling with 1-20 carbolic acid solution, should have a narrow smooth point and a ridge on the barrel to prevent the fingers slipping off. An inch of india-rubber tubing on the point may be used. If it is impossible for some one else to use the syringe, a Higginson's aural syringe is used by the patient himself. If giddiness is produced, the ear should be syringed with the patient lying down, and assurance given that it is of no importance and that it will soon pass off. Inflation with Politzer's bag, at first daily, with gradually increasing intervals, will be useful in keeping the Eustachian tube patent, preventing adhesions in the middle ear, clearing away discharge, and improving the hearing.

If the discharge is offensive, stronger antiseptics should be used, such as 1-4000 perchloride of mercury, or lysol $\frac{1}{2}$ per cent. The syringing may be preceded by the instillation for ten minutes of perhydrol, 10 vol.

In some cases, especially if the perforation is large and the mucous membrane swollen, the following spirit drops instilled for ten minutes after syringing will be beneficial :—

R Pulveris Acidi Borici

3j | Alcoholis

3iij

At first ten drops should be diluted with an equal part of hot boiled water, and if no pain is produced, the solution should be gradually increased in strength by lessening the amount of water, until it can be used pure.

If the perforation is in the top of the membrane (Shrapnell's membrane), it may be necessary for the surgeon himself to use an intratympanic syringe, the nozzle of which is passed through the perforation.

As improvement occurs, the intervals between the syringing should be gradually increased.

If after a few months the ear, although improved, remains stationary and the discharge palpably comes from the middle ear only, the cleansing treatment should be continued ; but if the discharge is still present, and if pus can be drawn from the antrum with Peter's magnifying speculum, the radical operation is indicated. If the hearing is good and the ossicles appear to be intact, they should be left.

Fig. 26.—Left Temporal Bone. The dotted lines and the posterior and superior outlines of Macewen's triangle show the amount of bone removed in performing the radical post-aural operation.

If the patient states that the hearing is markedly but temporarily improved directly after syringing, it means that a cotton-wick "*artificial membrane*" placed against the ossicles or their remains will improve the hearing. The wick should be about one inch in length, and made of double cyanide wool. A piece of the wool is evenly pulled out, laid on hot boracic acid solution, and carefully rolled up. The calibre should be such as not to fill the meatus completely. The tip should be dipped in paroline to prevent drying. A straight pair of untoothed forceps is used for its introduction. At first the patient should wear it for one hour a day, the time being gradually increased, hour by hour, until it can be worn all day. It should always be removed at night. If pain is produced the use must be discontinued, and after a time a further trial be made. The patient will get very expert in its use, and will be able to put it into the proper position more surely and quickly than the surgeon. It can often be used with marked benefit after the radical operation has been performed.

If there is much discharge the wick cannot be used, and if there is slight discharge the cleansing treatment should be continued.

Polypi and *Granulations*, unless malignant, indicate either neglect or caries of some part, and it is often impossible to say which. Some cases which look as if operative treatment will be necessary, rapidly heal up when the thorough cleansing treatment is used.

If a polypus, which is simply overgrown granulation tissue, project into or fill the meatus, it should be removed under a general anæsthetic and with all antiseptic precautions, by twisting, snaring, or curetting. The site from which it is growing should be gently curetted. In so doing carious ossicles may be removed. The meatus is afterwards lightly packed with iodoform ribbon gauze, and a gauze and wool dressing is applied. The dressing should be changed daily. If healing does not occur, even after a return for a short time to the cleansing treatment, and pus can be drawn out of the antrum with Peter's speculum, the radical operation will be required.

Granulations should be lightly touched with nitrate of silver, or chromic acid crystals, both of which can be fused on a probe. It will, however, often be necessary to curette the middle ear thoroughly under an anæsthetic.

Masses of epithelium, or so-called *cholesteatomata*, will often be seen to occupy the middle ear, with or without granulations. The masses can be got rid of by instilling warm perhydrol, 10 vol., for ten minutes before syringing. After removal, healing may occur under ordinary cleansing treatment, but frequently great destruction of parts is found, with implication of the attic, antrum, and mastoid cells—especially if the perforation is in Shrapnell's membrane—and demands the radical post-aural operation.

Caries of the Ossicles is very commonly found in chronic suppuration: the descending process of the incus in inferior perforation; and the head of the malleus and body of the incus, often associated with caries of the outer attic wall, in perforation of Shrapnell's membrane. Complete loss is also seen. Treatment as for chronic middle-ear suppuration. Removal of carious ossicles, with or without removal of the outer attic wall through the meatus, is not successful in stopping a middle-ear discharge, for the antrum is usually affected also, and they are removed during the performance of the radical operation.

With any of the above local conditions there may be signs of antral or mastoid implication which will demand a prompt radical operation; or there may be intracranial complications, when the radical operation should always be performed as a preliminary; for then not only is the origin of the trouble dealt with, but signs of extension from some part of the exposed cavities will show the way to the intracranial complication, the site of which is often doubtful.

Facial Paralysis may recover under treatment ; if it is permanent, the nerve may be joined to the hypoglossal, but the results are not encouraging.

The Internal Ear or Labyrinth is occasionally implicated. The chief symptoms characterizing the complication are increased and profound deafness, giddiness, vomiting, tinnitus, and nystagmus. In tuberculosis of the middle ear, implication of the labyrinth may be a quiet process. The labyrinth can be attacked surgically after a wide radical operation has been performed.

It may be said briefly that the radical operation consists in opening the antrum, tracking and removing disease wherever it may be found, removing the outer attic wall, clearing out the middle ear, and laying the antrum into the meatus by removing the posterior meatal wall. The dotted line in *Fig. 26*, and the posterior and superior outlines of Macewen's triangle, show the amount of bone which is removed in performing the operation.

Injury.—The membrane may be ruptured by direct or indirect violence. If by direct, the meatus should be purified, and a double cyanide gauze dressing in the meatus and over the ear should be applied.

If by indirect violence, such as condensation of the air in the meatus from explosion or blows, the deep meatus should not be syringed or touched, but the cartilaginous meatus, after being painted with iodine in alcohol $2\frac{1}{2}$ per cent, should be lightly plugged with gauze wrung out in 1–2000 perchloride of mercury, and changed daily until healing is complete.

If sepsis occurs, the treatment will be the same as in an acute inflammation of the middle ear.

In fracture of the bone involving the middle ear, thorough purification of the meatus, auricle, and side of the head should be performed, and a large double cyanide gauze dressing applied.

Sarcoma.—Sarcoma of the temporal bone, involving or starting from the middle ear, demands the widest possible removal in as early a stage as possible, and the application of radium ; but often the progress is so rapid that palliative treatment is all that can be done.

Syphilis.—The middle ear is sometimes affected by the specific inflammation in the nasopharynx producing Eustachian obstruction, or even spreading along the tube to the middle ear. Ordinary anti-syphilitic treatment and regular inflations with Politzer's bag will clear up the trouble. The nose-piece of the bag should be purified and kept distinct, and afterwards burnt, or a piece of drainage tube can be used in place of the nose-piece.

Tuberculosis.—Early tuberculosis of the middle ear is characterized by the painless onset of deafness, usually unilateral, associated with a red swollen condition of the membrane resembling that found in painful acute inflammation ; in other words, from the appearance of the membrane one would expect the patient to be in great pain ; but discomfort only is complained of. The infection may be secondary to tuberculosis of the lungs or of the nasopharyngeal tonsil (adenoids) or tuberculous infection of the nasopharynx, especially in infants. The disease may progress very rapidly, attacking the bone, producing facial paralysis, mastoid disease, caries or necrosis of the labyrinth, and extension to the meninges, spreading through the diploë. Glandular infection occurs early.

The local treatment, combined with sanatorium and general treatment in the early stage, is to purify the meatus and keep an antiseptic dressing on it. The discharge is slight unless further infection occurs, when it becomes profuse and offensive, requiring frequent syringing with 1–4000 perchloride of mercury, or lysol $\frac{1}{2}$ per cent.

If adenoids are present they should be removed. If there are signs of bone implication the ear should be turned forwards and all affected bone freely removed, the resulting wound being lightly stuffed with iodoform gauze, and

allowed to heal from the bottom. If the labyrinth is attacked it may be dealt with after a wide radical operation has been performed.

The affected glands should be removed at a separate operation. Tuberculin treatment may be tried.

If the facial nerve is completely destroyed, the distal end may be joined to the hypoglossal. (See also SPECIFIC THERAPY, and PHTHISIS.)

IV.—INTERNAL EAR.

Anæmia.—Tinnitus and deterioration of hearing due to anæmia or to great loss of blood yield to general treatment.

Congestion.—Deafness and tinnitus are seen in patients who live too well, take too much alcohol and tobacco, and have no exercise. The treatment consists in strict dieting, abstinence from alcohol and tobacco, regular exercise, massage, Turkish baths, and calomel purgation.

Deaf-Mutism.—Occasionally in those cases in which the deafness is due to chronic suppuration of the middle ear, the hearing may be improved by treatment sufficiently for the patient to acquire speech in the normal way. In a few cases in which the deafness is due to Eustachian obstruction caused by adenoids, the removal of the growth and subsequent inflations will be followed by the best results. In the great majority of cases, which are due either to malformation or incurable disease of some necessary part of the hearing apparatus, speech will have to be acquired by the teaching of lip-reading according to the German method. Tuition should begin about the age of five years.

Preventive treatment consists in avoiding the marriage of those in whose family deaf-mutism, due to malformation, is plainly hereditary, and of those who are consanguineous and in whose families there are signs of degeneration, such as deaf-mutism, epilepsy, idiocy, or lunacy.

Drugs.—Those which most commonly cause deafness are quinine, salicylate of soda, nicotine, alcohol, lead, and arsenic, including salvarsan. The treatment consists in avoidance, especially in those who are already deaf.

Quinine deafness is common among those who live in malarious districts; yet the drug is often taken as a prophylactic in a very haphazard way. The deafness and tinnitus are often transitory, but if the drug is persisted in, incurable deafness of varying intensity may be produced. The evil effects on the hearing may be prevented or lessened by combining it with dilute hydrobromic acid in doses of from $\frac{1}{2}$ dr. to 2 dr. with each dose of quinine, or by giving the quinine hypodermically; arsenic should be tried as a substitute in those who are susceptible.

If *Nicotine* is traced as a cause, it should be absolutely prohibited, and courses of strychnine given. In all cases of deafness, smoking is distinctly injurious.

Lead deafness should be treated by sulphate of magnesia, internally, and the taking of proper precautions by those who work with it.

Exudation.—This occurs in leukæmia and mumps. Treatment consists in rest, blistering behind the ear, and the administration of iodide of potassium. Hypodermic injection of pilocarpine once a day for ten days may be tried. The deafness in typhoid fever is probably a toxic neuritis, and usually passes off without treatment about the sixth week.

Hæmorrhage.—This is apt to occur in whooping-cough, anæmia, nephritis, and diabetes. The treatment is unsatisfactory. It should consist in treatment of the cause, and rest, with iodide of potassium internally. Daily hypodermic injections of pilocarpine for ten days may be tried.

Inflammation.—This may be due to extension from the middle ear or from the meninges in cerebrospinal meningitis. If it is due to the former, complete rest, both general and functional, should be insisted on; the back of the ear

should be blistered, hot fomentations applied over the ear, and a calomel purge given. If the symptoms of giddiness, vomiting, markedly increased deafness, and high temperature, with lateral headache, persist, the outer wall of the labyrinth should be exposed by a wide radical operation; if improvement does not occur in three days, the labyrinth will have to be opened and drained through the vestibule, both in front of and behind the facial nerve. It may be necessary to remove the entire labyrinth. Not infrequently caries will be found in some part of the outer labyrinthine wall, requiring free opening and drainage, or sequestration of part or the whole of the labyrinth may be found and removed. In cases due to cerebrospinal meningitis, treatment consists in complete rest, with blistering behind the ear and a calomel purge. Iodide of potassium should be given internally, and pilocarpine hypodermically, daily for ten days. The prognosis is often very bad, the disease in young children frequently resulting in complete deafness and consequent mutism, necessitating lip-reading lessons.

Injury.—Punctured wounds or fracture at the base of the skull involving the labyrinth should be treated by strict purification of the ear, meatus, and side of the head, and the application of a double cyanide gauze dressing. The result as regards hearing is very bad, and treatment is futile. Excessive condensation of the air in the meatus may be transferred to the labyrinth through the ossicula chain, as in explosion and blows, producing concussion of the auditory nerve in the labyrinth. The treatment is preventive. Those who are likely to be exposed to explosions, such as sailors, soldiers, and sportsmen, should have healthy ears, noses, and throats, and should plug the ears with a mixture of modelling clay and fibre. The "clay fibre," as it is called by Sir William Dalby, who originated it, may by a little manipulation be made soft and pliable, and therefore fits any ear. A fairly large piece should be used. Sportsmen should protect the left ear, which is the one always affected, unless shooting takes place from the left shoulder. Recovery may take place more or less on rest: other treatment is useless.

All who work in a constant noise, such as boilermakers, and those in the navy who are exposed to the constantly repeated high-pitched penetrating report of the lighter guns, gradually become deaf. The variety of deafness has been likened to the blindness produced by excessive exposure of the eyes to a bright light. The treatment is prevention, by wearing the clay fibre. When the deafness is once established treatment is useless.

Ménière's Disease is a hæmorrhage into the labyrinth and is decidedly rare, but the symptoms are common to many labyrinthine troubles which occur by injury, foreign bodies, cerumen, spread of infection, mumps, syphilis, diabetes, kidney disease, circulatory troubles, cerebrospinal meningitis, leukaemia, anaemia, auditory nerve tumour, and geniculate ganglion inflammation. A cause for the labyrinthine symptoms should always be carefully searched for, and even in the most unlikely cases a Wassermann test should be made if no other cause can be found. Treatment depends on the cause. If no cause can be found, treatment should be directed to anything which might cause increased tension. A milk diet is often valuable. Dilute hydrobromic acid, in doses from 40 minims to 1 or 2 dr. three times a day, should be given, and counter-irritation behind the ears by means of blistering should be kept up for a considerable time. Very rarely the symptoms call for an operation on the labyrinth.

Neurasthenia.—Those who have undergone severe mental strain or worry for a great length of time, without proper rest and exercise, often suffer from deterioration of hearing, and sometimes tinnitus. The treatment consists in rest, change of surroundings, and the giving of strychnine. Sometimes it is necessary for patients to undergo a formal rest cure. A great shock may cause sudden complete functional deafness. Rest and change, with the application of faradism

behind the ears, will, as a rule, effect a cure ; sometimes, however, treatment has no effect ; but the hearing often returns spontaneously, perhaps after a counter-shock.

Otosclerosis.—This disease is a thickening of the bony labyrinth, producing fixation of the stapes. It is the cause of most of the intractable cases of deafness. It is more frequently seen in women, is very insidious in its onset, is not due to catarrh, although this may also be present ; there is no Eustachian obstruction or depression of the membrane. Hearing better in a noise is usual, and is often noticed from the onset of the deafness. Sometimes the deafness remains stationary for a long time. Heredity is a marked feature. Child-bearing has a distinctly prejudicial effect ; in fact, some patients date the onset from a confinement. Absolute deafness does not result.

There is no treatment which can be said to have a really distinct effect upon it. Phosphorus in doses of $\frac{1}{100}$ gr. in the middle of a meal, twice a day, for six weeks off and on, may be tried in the early cases. If catarrh is present, it should be treated in the usual way. The patient should live as healthy a life as possible, and in the later stages artificial aid will be necessary in the form of a trumpet, speaking-tube, or electrical aid. It is a good plan for the patient to go to a trustworthy maker and try the various forms of aids, as it is impossible to say which will be most useful. All the patients unconsciously learn a certain amount of lip-reading, and it is wise to have lessons from a good teacher fairly early in the course of the disease. Co-existent anæmia and rheumatism should be treated.

Senile Deafness.—About the age of sixty a gradual deterioration of hearing, without tinnitus, takes place. Local treatment is useless. Treatment directed to the general health and to arteriosclerosis in particular is all that can be done.

Syphilis.—In congenital syphilis, the treatment consists in repeated blistering behind the ears continued for many months. One ear should be blistered at a time, in order that the patient may be able to sleep comfortably. Iodide of potassium and mercury are quite useless. If the deafness becomes absolute, lip-reading should be taught.

In secondary acquired syphilis, the patient should be placed under the influence of mercury and salvarsan as soon as possible. Blistering should be applied behind the ears, and hypodermic injections of pilocarpine should be given every day for a fortnight.

In the later stages of the disease, deafness may be associated with facial paralysis and giddiness. Recovery usually takes place under inunctions of mercury, iodide of potassium internally, and blistering behind the ear.

Internal-ear deafness, probably due to sclerosis of the auditory nerve, is sometimes associated with tabes, and may be the first sign ; or a gradual onset of nerve deafness, with a continuous hissing, tinnitus, sometimes with giddiness, without any other nerve complication, may be met with.

The treatment is on general antisyphilitic principles, but it is not certain that salvarsan should be used for the auditory nerve troubles in the later stages ; more experience is necessary.

Tinnitus.—This is merely a symptom ; treatment of the cause will do all that can be done. The cause is sometimes difficult to find, and requires the most patient local and general investigation.

In nervous patients the unavoidable noises are exaggerated, and sedatives are required. Bromide of potassium or dilute hydrobromic acid, in $\frac{1}{2}$ -dr. to 2-dr. doses three times a day, is sometimes useful. Strychnine should be given to those who are run down. Anæmia, and cardiac or renal disease, will require treatment. Patients often think that the noises mean some brain trouble, and that they are going to become insane ; reassurance on this point is often a great relief. If the noises take a purposeful form, such as the hearing of voices or airs,

it is a sure sign that the patient is or will be insane, and the friends should be warned. A history of lunacy in the family can usually be obtained.

Tuberculosis.—The infection of the internal ear invariably spreads from the middle-ear tract. The most usual sites of attack are the promontory and its neighbourhood, and the external semicircular canal where it forms the inner boundary of the opening of the antrum into the middle ear. The infection may spread through the diploë round the bony labyrinth, producing necrosis of part or whole. The treatment is removal after a wide radical operation has been performed.

Vertigo.—True auditory vertigo is characterized by the moving of objects round the patient in one direction or another, with falling or staggering, and the association of tinnitus, vomiting, and nystagmus. It is only a symptom of labyrinthine trouble, and the treatment depends on the cause. Broadly speaking, rest, a calomel purge, light diet, and dilute hydrobromic acid in large doses are indicated.

A. H. Cheattle.

ECLAMPSIA.—This is a disease characterized by two striking symptoms : epileptiform convulsions, and coma between the convulsions. Coma is an essential part of the disease, and in a fatal case there may occasionally be coma without fits.

It is generally agreed that eclampsia is due to a toxin circulating in the blood-stream. This toxin acts as a powerful vasoconstrictor, and the blood-pressure becomes markedly raised. When a definite and lasting rise of blood-pressure is detected in the latter months of pregnancy, it strongly suggests impending eclampsia, because during the whole course of normal gestation there is little or no alteration in arterial pressure. The toxin constricts the renal arterioles, and so alters the circulation of blood through the kidneys that the secretion of urine becomes greatly diminished, and finally entirely arrested. The blood-pressure is highest when the anuria is complete, and in order to get urine secreted again it is absolutely necessary to lower the pressure. As a result of the altered circulatory conditions in the kidney, and because the toxin acts as a protoplasmic poison, albumin appears in the urine ; sometimes in small amount only, but more usually in sufficient quantity to boil solid in a test tube. Very occasionally the urine is free from albumin, or this is present only in the merest trace during the fits. Albumin in the urine of a pregnant woman is generally looked upon as the danger signal of eclampsia, and as soon as it is detected every effort must be made to arrest the progress of the toxæmia before it culminates in convulsions. The quantity of urine is nearly always diminished when eclampsia is impending, and this symptom may be noted before the appearance of albumin. Another constant and striking feature in eclampsia, and in impending eclampsia, is that the urea secretion is *always* diminished. This points to a serious disorganization of the metabolism.

Eclampsia may come on during pregnancy before labour has begun, and then, under proper treatment, the fits and coma may pass off, and delivery take place later with no untoward symptoms. But matters do not often end so favourably ; usually labour commences, and the fits increase in number and severity. Generally speaking, indeed, the earlier the symptoms arise during pregnancy the greater the danger. Most commonly eclampsia attacks the patient during the first stage of labour, and then the treatment is more likely to be successful, especially if labour goes on rapidly, or can be hurried on. In other cases the fits start after delivery is completed—*post-partum eclampsia*. Death from puerperal eclampsia may take place from coma with heart-failure, even after one fit ; from hyperpyrexia ; or from late bronchopneumonia, set up by the buccal secretions or by particles of food getting into the bronchial tubes.

The prevention of eclampsia is more hopeful than its cure, but one must admit that the disease cannot always be prevented even when its approach is suspected. The fits may come on with startling suddenness at a time when the patient is apparently in perfect health and under the eye of a competent physician. But in the vast majority of cases the onset is heralded for several days, often for longer, by certain well-recognized toxæmic symptoms, such as severe headache, dimness of sight, giddiness, vomiting, epigastric pain, and swelling of the face and limbs. Every woman, when she comes to engage a doctor for her confinement, should be carefully warned by him of the possibility of such symptoms

arising in the latter months of pregnancy, and, if she suffers from any of them, should clearly understand that a sample of her urine must immediately be sent for examination. Otherwise it is highly probable that the first announcement of the disease will be a fit.

There are certain features which indicate a *bad prognosis* in eclampsia:—Œdema absent, or present to only a slight degree; coma, if markedly present after the first fit, or when deep and prolonged; pulse continuing rapid between the fits; albuminuria in small amount only, or absent during fits; urea excretion less than one per cent; temperature high and not remitting; jaundice, if associated with deep coma and anuria; anuria complete, and persistently so under treatment. In *post-partum* eclampsia the prognosis is not invariably bad, especially if the first fit occurs within a few hours after delivery; occurring later, it is much more dangerous, particularly in multipara—the prognosis is then bad. Maniacal symptoms and extreme restlessness seem to be of favourable significance. In any case the prognosis is greatly improved if the secretion of urine can be fully re-established, and, more important still, if the urea output can be made to increase steadily. The least dangerous cases are those in which only a few fits occur during a rapid natural labour. In the eclampsia of pregnancy, if the fœtus dies the result for the mother is generally favourable; indeed, fœtal death at any time in the course of eclampsia seems to improve the mother's chances of recovery. The maternal mortality under the best treatment is still about 20 per cent, and 50 per cent of the infants are lost.

1. Treatment of Albuminuria in Pregnancy (Threatened Eclampsia).—Since it is one's duty to try and prevent eclampsia, the treatment of albuminuria during pregnancy must be considered first. Slight albuminuria towards the end of pregnancy or at the commencement of labour may in no way indicate impending eclampsia. The symptom may be due to pressure alone, as in twin cases. With a marked reaction for albumin, diminished quantity of urine, low gravity—pointing to a lessened urea excretion—and possibly casts, the case must always be treated as one of threatened eclampsia. The blood-pressure in the great majority of these cases is considerably raised—150 to 180 mm. Hg or higher—the peripheral vessels are contracted, and there is œdema of the face, neck, limbs, and often of the body generally. The œdema may be of a myxœdematous nature, not pitting on pressure. The blood-pressure should always be accurately estimated in these cases by means of a sphygmometer of the Riva-Rocci type—Martin's modification is convenient and easily used. The blood-pressure chart is the most reliable index of the influence of treatment.

First, always put the patient to bed. Chills are then avoided, and the beneficial effect of rest in lessening metabolism is secured. It is well to know from day to day how much urine is being secreted, and its gravity. The diet of these patients is a very important matter. When there are ominous symptoms, such as high blood-pressure and impaired vision, give milk and nothing else. If improvement follows, one may soon add Benger's food, Allenburys' diet, milk puddings, etc. As constipation is certain to be present to a greater or less extent, begin by giving a large enema of soap and water to wash out the bowel. A dose of compound jalap powder (30 to 60 gr.) should be given, and, if necessary, repeated next day. At all events a regular aperient dose must be given every night so long as the patient is under treatment; a pill containing aloin, calomel, and extract of belladonna, $\frac{1}{4}$ gr. of each, followed in the morning by a saline such as magnesium sulphate, answers admirably. When there is great general œdema, elaterium ($\frac{1}{4}$ gr.) acts better than anything. It is also well in severe cases to employ rectal lavage with hot water from time to time. When renal

activity is unsatisfactory, a mixture containing acetate of potash (30 gr.), and solution of ammonium acetate (2 to 4 dr.) may be given four-hourly. When the blood-pressure is strikingly high, no drug can compare in usefulness with potassium iodide. With the patient in bed, 10-gr. doses thrice daily will seldom fail to lower the pressure and greatly benefit all the symptoms. The iodide should be well diluted, and may be combined with pepsencia. Spirit of nitrous ether may be given in addition in drachm doses. The action of iodide in these cases is very subtle, probably an indirect one through the thyroid gland. For many years it has been known to exert a specific effect on pregnancy albuminurias.

In 1901 the writer suggested the use of thyroid extract in the toxæmic albuminurias of pregnancy, and in eclampsia. Thyroid powerfully stimulates the metabolism, and increases urea excretion. For these reasons, and because it is a vasodilator and diuretic, it tends to bring many of the abnormal circulatory and urinary features of impending eclampsia nearer to the normal again. For this purpose 5 gr. of the extract three or four times daily is sufficient.

The albuminuric patient should drink plenty of Vichy, Contrexéville, or plain water. The skin must be kept acting well. Turkish baths may be used, or the patient may have rather long immersions in a hot bath and be put back to bed in a warm blanket. In more threatening cases a "hot wet pack" may be advisable to produce full action of the skin. Chloral (15 to 30 gr.), bromide (30 to 60 gr.), or barbitone (*veronal*) (8 to 12 gr.), may be used at bedtime to relieve restlessness and promote sleep. Almost all the cases treated in this way escape eclampsia.

In a case of albuminuria with severe toxæmic symptoms, accompanied by very high blood-pressure and persistently low urea excretion, if little or no improvement results from treatment, labour should be induced. This is perhaps especially called for in primiparæ, and may be done, in certain circumstances, even before the viability of the child. Induction of labour is a slow process, but there is generally time to employ it successfully. In a very severe pregnancy toxæmia, however, if the patient shows signs of jaundice, and more particularly if her sight becomes worse and worse, it is perhaps safer and better practice to anticipate the onset of convulsions by *immediate* removal of the uterine contents. This is best done by means of abdominal Cæsarean section.

2. Treatment of Convulsions in Pregnancy, Labour, or the Puerperium (Actual Eclampsia).—The treatment of actual eclampsia is simply an extension of the methods mentioned above, and, naturally, the more alarming the symptoms the more active must the treatment be. If the patient is seen during a fit, give chloroform to control it temporarily. Then give a hypodermic injection of morphia sulphate, $\frac{1}{2}$ gr., with or without atropine.

Morphia must be given in large doses ($\frac{1}{2}$ to $\frac{3}{4}$ gr.), for its action is then that of a powerful vasodilator, and it corrects the abnormal circulatory conditions in the kidney in eclampsia, thus enabling the organ to secrete urine again. It is, of course, also an eminently suitable remedy to soothe the nervous system and subdue restlessness. No single drug is so valuable in this disease, if enough is given. If the fits continue, give another $\frac{1}{2}$ gr. one or two hours after the first dose, and go on giving the drug in similar doses, every two hours if need be, to keep the patient quiet. Two or three grains may have to be given in twenty-four hours, but with the other methods of treatment employed, it is seldom that nearly so much is required. During each fit chloroform should be given, and it is only when the patient is under the influence of the anæsthetic that she should be examined to ascertain the stage and progress of labour. Care must be taken that the tongue is not bitten during a fit. This is prevented by means of a cork, or piece of wood, placed between the teeth. No medicine or food

must be given by the mouth until the patient is fairly conscious, or it may find its way into the lungs and set up pneumonia. Keep her on her side while she is deeply comatose, so that saliva may trickle out of the mouth instead of possibly finding its way into the larynx. Many cases of eclamptic convulsions are successfully treated, in general practice, simply by the methods already mentioned. The practitioner gives a powerful purgative, washes out the rectum, uses chloroform if necessary, and injects half a grain of morphia. He may also order a "hot wet pack"—stone ginger-beer bottles filled with hot water, put into wet socks, and packed round the patient. If labour is going on he probably hurries it up, using forceps towards the end. He lets the patient bleed as freely as possible in the third stage, and does not give ergot. Possibly he advises that chloral be given later on. There may be a fit or two afterwards, but the recovery is uninterrupted. These are mainly cases where the fits occur actually during labour—are perhaps initiated by some definite external stimulus.

The question of *bleeding* as a valuable therapeutic measure in eclamptic cases must be referred to. If the blood-pressure when estimated, as it should be in every such case, is found to be 150 to 180 mm. Hg or higher, one should bleed freely from the arm. In almost every severe case of eclampsia, bleeding from a large venous trunk is physiologically the correct thing, since it is the easiest way—short of bleeding the kidney directly—of emptying the congested renal veins and thus enabling the kidney to resume its function of secreting urine freely.

Recently *Veratrone*, a non-alcoholic solution of the active principles of *veratrum viride*, specially prepared for hypodermic use by Parke, Davis & Co., has been employed mainly for the purpose of controlling the fits. The full dose is 1 c.c., which equals 20 min. of tincture of *veratrum viride* (*B.P.* 1885). When the pulse-rate is rapid, the blood-pressure high, and fits are frequent, *veratrone*, injected deeply into the muscular tissue of the thigh, produces very definite results. The pulse-rate may drop to 50–60 per minute, and the pressure fall 40–60 mm. of Hg. When the blood-pressure is lowered by *veratrone*, the pulse-rate is also greatly slowed, hence the drug profoundly depresses the heart muscle. It also exerts a powerfully depressant effect on the motor tracts of the spinal cord, and likewise produces a remarkable lengthening of the contraction of the voluntary muscles. For these reasons the convulsive seizures may be quite prevented. *Veratrone* probably also depresses the vasomotor centre, and, by enlarging the arterial calibre, will, like morphia, rapidly re-establish the secretion of urine. If the blood-pressure again rises considerably, a second injection is desirable, for the fits may then return. The slow pulse is here an index of lowered pressure; if under 60 per minute there is comparative safety. Should the drug cause alarming depression, strychnine ($\frac{1}{30}$ grain) may be injected hypodermically. In cases where *veratrone* is used, it is seldom that bleeding is necessary or advisable. Morphia is not contra-indicated, however; the two drugs may be usefully given together.

The principles of treatment, then, in eclampsia, are shortly as follows: (1) *Control the fits*. To fulfil this indication chloroform may be necessary at first, but preferably use morphia or *veratrone*, with a free hand. (2) *Get the toxin out of the body*. Bleeding removes some toxin; it is by means of the kidneys, bowels, and skin that the remainder is removed. But this work is mainly done by the kidneys, and the complete or nearly complete suppression of urine is really the one symptom which must be promptly and vigorously treated. The toxin has acted on the renal vessels in such a manner that the steady flow of blood through the kidney, essential to a free secretion of urine, is interfered with. If one can get venous blood out of the organ, and at the same time produce complete relaxation of the systemic arteries and arterioles, one produces

the desired result of getting blood to flow freely again through the renal glomeruli. Morphia, in these large doses, is the ideal vasodilator because it acts so swiftly. Thyroid extract, 30 to 40 gr. every three or four hours, to produce "thyroidism" rapidly, is equally efficient, and should be used after the morphia when the patient can swallow. Veratrone appears to act in a similar manner by lowering the blood-pressure. (3) *Get the uterus emptied if the fits cannot be satisfactorily controlled.* This is a principle of treatment mentioned here only in order to condemn *accouchement forcé* in all but very exceptional cases. It is good practice often to accelerate labour cautiously, but it should be done gently, by means of manual dilatation, or by the use of the de Ribes' bag, followed by the application of the forceps.

In the *more severe cases*, the following methods of treatment should be employed in addition to morphia, thyroid, etc. :—

1. *Bleeding from a vein.*—The median basilic vein is chosen. If the patient is not comatose, give chloroform, and apply a bandage round the upper arm to make the forearm veins stand out. Make an incision about an inch long over the vein, separate it from its tissues, and pass a loop of silk underneath it. This is done because, after drawing off blood, one may transfuse hot saline into the vein. Open it and bleed to the extent of 10, 15, or 20 ounces, judging by the pulse, or preferably by the blood-pressure, when sufficient blood has escaped.

2. *Subcutaneous infusion of hot saline solution.*—Twenty ounces or more of hot normal salt solution are run slowly into the loose tissue under the mamma, axilla, or inside of thigh. Sterilize the skin at the site of injection with iodine. The saline is made by adding one teaspoonful of common salt to each pint of boiled water cooled to a temperature of 103°–105° F. One uses a glass funnel, a length of tubing, and a sharp-pointed metal cannula. The funnel is elevated about four feet, and the fluid flows readily into the areolar tissue, and is quickly absorbed. Sometimes the warm saline is run directly into the vein, after bleeding. Recent experience has convinced the writer that this method is not unattended with danger in eclampsia, owing to the blood changes, and that the subcutaneous injection is an equally useful and perfectly safe alternative. When a quantity of hot saline is thus introduced into the circulation, the effect is to relax the contracted arterioles, and lower the blood-pressure. In this way one of the factors essential to the re-establishment of diuresis is brought into action. Therefore such an infusion acts as a powerful diuretic in eclampsia.

3. *Washing out the stomach with hot water.*—While the patient is under chloroform, a soft rubber tube is passed into the stomach. Hot water at a temperature of 110°–115° F. is poured down the tube through a funnel until the stomach is quite filled. Then the tube is pinched between the finger and thumb so as to keep it full of water. This is important, because it is only by leaving the stomach tube full of water that it will act as a syphon when the funnel is inverted. Wash out several times, and leave the hot water in the stomach for several minutes at a time. This is, in the writer's opinion, a valuable method of treatment. The mucous membrane of the stomach excretes into its cavity toxic substances which are present in the blood. This is the way in which snake venom and drugs like morphia are partly excreted. The same thing almost certainly happens with the toxin of eclampsia, so the stomach washing carries a certain amount out of the system. Again, in the stomach and intestines there is an enormous area of blood-vessels which, if fully dilated, will readily draw away blood from adjacent organs such as the kidneys. Very hot water in the stomach acts *directly* on this large vascular area, and the capacious splanchnic vessels become relaxed. This is a practical method of getting blood out of the renal veins.

4. *Leaving a solution of magnesium sulphate in the stomach.*—Before the withdrawal of the tube, a concentrated solution of sulphate of magnesia (4 to 6 oz. dissolved in 5 to 6 oz. of water) is poured through the funnel and left inside the stomach. In case the patient is apt to vomit after this, the chloroform anæsthesia is prolonged for a little. The very free purgation from the intestine following this dose is a most useful effect, and it is more precise and altogether better than croton oil. Eclamptic patients are generally very constipated, so in addition to leaving a purgative in the stomach in this way, one should also wash out the bowel frequently with hot water.

Some patients become highly restless, noisy, and almost maniacal, instead of lying semi-comatose, as is usually the case. Then chloral is useful. It may be given by the mouth (30 gr.) if the patient can swallow, or per rectum* (60 gr.). It also acts well hypodermically (6 to 10 gr. in 1 dr. of distilled water).

The treatment of *post-partum* eclampsia is the same as that mentioned above. If fits occur frequently and anuria is persistent, it is possibly worth while to expose each kidney in turn, and either decapsulate it after the manner of Edebohls, or bleed it freely by cutting deeply into its lower border.

ECLAMPSIA NEONATORUM.—(See CONVULSIONS, INFANTILE.)

ECTOPIA TESTIS.—(See TESTICLE, UNDESCENDED.)

ECTROPION.—(See EYELIDS, DISEASES OF.)

ECZEMA.—It is absolutely impossible to describe the treatment of eczema as a whole. The term is constantly and grossly abused, and the writer has for long taught that the more one knows about skin diseases, the fewer cases he finds it necessary to label "eczema."

Many cases, many more than are generally suspected, are due to some external irritant to which the patient is consciously or unconsciously exposed, and the removal of this is essential to success in treatment. Some are connected with the patient's work, and are notorious irritants, such as sugar in the baker's eczema, soda in the washerwoman's, and various chemicals in the photographer's. In plants, too, one has an enormous number of possible irritants, and all "eczemas" of the exposed parts should suggest to the physician the possibility of their having been brought about in this manner.

The treatment, then, consists in finding out what has produced the dermatitis, and, if possible, avoiding it; the treatment of such cases as one is unable to find a cause for resolves itself into purely symptomatic management. The chief complaint in an acute dermatitis is itching, and for this there is no application so generally valuable as a lead and tar lotion.

Liquoris Plumbi Subacetatis	āā 3ij	Aquam	ad 3vj
Zinci Oxidi	3ij		

If the acute stage is past, but there is considerable exudation, it will probably be found that a paste is the most convenient application. Lassar's paste:—

R. Zinci Oxidi		Vaselini	
Pulveris Amyli	āā 3ij		3ss

has deservedly won for itself great popularity in the treatment of "eczema."

In the scaly forms, ointments are indicated, and here once more tar takes a prominent place in treatment, used in a more concentrated form than in the acuter varieties. Common crude tar, fresh from the gas works, is a very valuable application in many cases. The part should be washed free from grease, and then the tar should be applied with a stiff painter's brush in *as thin a layer as*

* Experiments show that hydrated chloral is absorbed from the rectum quite as rapidly as after oral administration, in the cat.—AMERICAN EDITOR.

possible. It dries rapidly, and though it looks dirty it does not soil the clothes as ointments do. It is well to make a small experimental application in each case, for in a minority of cases tar acts as an irritant. If it causes no irritation on the trial spot it may be fearlessly applied to a large surface. In very chronic forms, where the case proves rebellious to ordinary treatment, it is often desirable to convert the chronic into an acute dermatitis, and this is best done by the application of caustic potash according to the method of Hebra. A piece of wool, dipped in liquor potassæ, is scrubbed vigorously to and fro over the patch until a number of red oozing spots appear. The potash is then washed off with warm water, and lead and vaseline ointment (emph. plumbi 1, vaseline 1) applied. The relief from itching following on this application is often marvellous, and although it is excessively painful at the time, patients receive so much benefit from it, that they usually return with the request that the application be repeated.

General Treatment.—While the relationship of indigestion to eczema is very much exaggerated, it is certainly the case that digestive disturbances aggravate an existing eruption and may cause it to persist, as its disappearance when the digestive functions are restored proves. These should therefore be inquired into, and suitable treatment prescribed. When there is no such disturbance, it is unnecessary to put the patient on any specified diet. Good plain food does no harm to anybody. But there are certain articles of diet which are particularly injurious to the inflamed skin. Of these, the first place is occupied by alcohol, and unless there are very urgent reasons to the contrary, patients with eczema should be total abstainers. Close on alcohol, as aggravating factors, come spices and condiments, chutney and curry running it very hard. Coffee, salted viands, and strong-tasted cheeses are less, though still, injurious, and the writer has met with a number of patients who were convinced that apples were harmful. He does not believe that this is generally the case, but it is perhaps worth mentioning, for in chronic cases the patient himself can do much to help on his own recovery by a close observance of those articles which experience shows him to be injurious.

Drugs have very little effect on dermatitis, and in particular arsenic is only valuable in those cases of dry scaly "eczema" which one has, as a rule, little difficulty in curing by other means.

Like other diseases, it has been attacked by electricity, and it seems certain that cases have benefited wonderfully under x-ray and high-frequency treatment, though it is obvious that these are applicable only in special circumstances, and are not likely to be adopted as a routine method. (See also GOUT.)

Norman Walker.

ELECTROTHERAPEUTICS.—While many methods of electrical treatment come solely within the domain of the specialist, in all probability more than half the disorders treated electrically are dealt with by such currents as are obtainable from a portable combined battery of medium size, with which everyone is more or less familiar.

It is with particular reference to the use of such a battery that the present article is written. More elaborate methods of treatment will not be described at length.

I.—APPARATUS.

Every dealer or manufacturer of electro-medical instruments has some favourite form of combined battery, and an inspection of their catalogues and stock will be more satisfactory than any description that can be given here.

However much they may differ in detail, they all have the same essential parts, which should receive careful inspection and testing before purchase. Speaking generally, the larger the cells composing the constant current battery, the more satisfactory will the instrument be in practical use.

For a portable battery, only dry Leclanché cells are used. The relation of weight and portability must of course be kept in view, and this, in most instances, will determine the size selected.

The number of cells required for the constant current will seldom, if ever, exceed thirty. Besides these, one or two, usually larger cells, will be provided to work the induction coil from which we obtain the faradic current.

The first essential is some means of regulating the force or strength of the currents when making electrical applications. This is of the greatest importance, and is a point in which many batteries fall far short of perfection. We will consider the constant current first.

Resistances, or rheostats, as they are called, are now little used for this purpose, on account of the superior advantages of the cell collector for batteries, and the sliding shunt resistance for controlling the current from the main.

Cell Collectors are of two kinds, single and double. The latter form has many advantages where the battery is in constant use; but for a portable battery, which is used only occasionally, and considering that the dry cells composing it have to be renewed every year or so, whether they are used or not, the single collector is all that is really required. It is simpler to work and to understand, and less likely to give trouble. It consists of as many brass studs as there are cells in the battery, and one extra, upon which the arm or crank rests when not in use. The cells are all joined together in series; that is, the zinc of the first cell is connected to the carbon of the second, and the zinc of the second to the carbon of the third, and so on. This leaves a free carbon, or positive pole, at the beginning of the series, and a zinc, or negative pole, at the end. The thirty-one brass studs—we are considering the case of a thirty-cell battery—are arranged in a circle. The arm or crank is pivoted on a point coinciding with the centre of this circle, and is of such a length that, as it is moved round, it makes contact with the studs in succession. The free carbon, or positive pole, is attached to the first stud, which is marked O, and also to the + terminal from which the current is taken. A wire is brought from the junction between the first and second cells to the next stud, which is marked 1, and so on all the way round—the zinc or negative pole being joined to the last stud, which is marked 30. The pin upon which the crank is pivoted is joined to the negative terminal. The crank must make contact with one stud just before it leaves another, but care must be taken not to leave it in contact with two studs for any length of time, as this would short-circuit one cell and rapidly exhaust it. The crank should offer a slight resistance to movement, and slide round smoothly, making light but sure contact with each stud as it passes.

It will be seen from the above arrangement, that whatever stud the arm is resting upon, as many cells are in use as are indicated by the number of the stud, and that this number of cells can be increased or diminished by a single cell at a time, thus avoiding unpleasant shocks to the patient. It is most essential that this part of the instrument be made with the greatest care if it is not to be a source of trouble at some future time—in all probability, at a critical moment.

While it would be possible to use a battery as above described for purposes of treatment by the constant current, it will be found more convenient and advisable to have a measuring instrument, and also a means of reversing the current. The wire from the stud marked O and that from the pivot of the crank are brought to the current reverser. This is made in different ways, but all have a handle which can be moved to one side or the other, which are marked N (normal) and R (reverse) respectively. When the handle is opposite N it means that the two terminals of the battery are + and - exactly as they are marked. If moved to the side marked R, the plus terminal becomes minus or negative, and vice versa.

The Galvanometer, or measuring instrument, should be looked upon as an essential rather than a convenience. It is to the electrotherapeutist what the measuring glass is to the chemist—the one means of ensuring accurate dosage. One of the wires from the current reverser is taken straight to one of the terminals, the other is brought to one terminal of the galvanometer; the other terminal of the latter is joined to the other terminal of the battery. In this way all the current passes through the measuring instrument, and when the handle of the reverser is put over, the flow of current in it is reversed also, which causes the pointer to be deflected in the opposite direction.

Galvanometers, or milliampèremeters as they are often called—the milliampère, or one-thousandth part of an ampère, being the unit of current employed in medical applications—are of two kinds, the magnetic, and the moving coil type. Until quite recently, all medical galvanometers were of the magnetic type. They were undoubtedly accurate, but laboured under certain disadvantages. They had to be carefully levelled and placed in proper relation to the magnetic meridian to bring the pointer to zero. They are easily affected by the presence of iron or other magnetic bodies near them, and the hand always takes some time to come to rest, which is inconvenient. They are rapidly giving place to the moving coil type of instrument, which, though more delicate and requiring careful treatment, is much to be preferred.

It reads accurately in any position, is quite independent of the earth's magnetism or the presence of magnetic bodies, and is "dead beat,"—that is to say, the pointer indicates at once the amount of current passing, without swinging to and fro for some time.

The danger is that it is very liable to damage if the terminals of the battery should be accidentally short-circuited, even for a few seconds. The pointer is flung over to one side, and if it escapes mechanical injury from this, it may have the moving coil damaged by the excess of current. This danger, however, is minimized by having an instrument which is provided with *shunts*. This not only greatly increases its range of usefulness, but acts as an efficient safeguard. The principle of the shunt is, that when a current has the choice of two paths in which to flow, it divides itself between the two, so that the current strength in each path is inversely proportional to its resistance.

The usual scale is five milliamperes by fifths, on each side of the centre. If we turn on the first shunt, marked 10, it means that only one-tenth of the total current passes through the moving coil, while nine-tenths pass through the shunt. A "100" shunt may or may not be provided, but there should always be one marked 0. When this is turned on it means that the whole instrument is cut out. If it is made a rule always to have this one in use except when it is desired to take a reading, it is impossible for the instrument to be damaged. It will be understood that, if the 10 shunt is in use, the reading on the dial must be multiplied by ten, when each division between 0 and 1 or 1 and 2 is equivalent to two milliamperes, and if the pointer swings over to the end of the scale, it means that a current of fifty milliamperes is passing through it.

It should be an invariable rule to turn the crank of the collector back to zero immediately the application is over. A battery or other generator of electrical energy never loses an opportunity of discharging itself, and such opportunities are easily afforded with wet cords and electrodes lying about.

The Induction Coil.—The other part of the combined battery is the induction coil, from which is derived the induced or faradic current. The great characteristic of the currents from an *induction coil* is that they are constantly varying. The pressure is always rising or falling, and even reversed periodically. The induction coil is probably the best known electrical device in use by medical men and others. In its simpler forms it is very inexpensive, and is quite efficient for the purposes for which it is intended. From the fact that it lends itself very readily to great variation in constructional detail, few instruments have been subjected to such numerous modifications; but it must be admitted that the results have not been commensurate with the trouble and ingenuity expended. Every imaginable form of interrupter has been devised, as well as various methods of winding; but the inherent defects of the coil remain substantially uncorrected.

The weak point of every coil is the interrupter—the great difficulty being to get one with a wide range of adjustment, which will work smoothly and evenly at all speeds. The least objectionable form is the one which is operated by a separate magnet. With certain adjustments, and also by adding inertia to the hammer by means of a special rod and sliding weight, almost any speed of interruption can be obtained, from one or two to one hundred or more, per second. Coils provided with this separate contact-breaker are usually of the sledge pattern, which is always to be preferred, since it permits of such good regulation to both primary and secondary coils. The secondary coil should be "tapped" at a point one-third from the beginning, and the wire brought out to a separate terminal. This enables one to use one-third, two-thirds, or the whole, as required; it is, in fact, equivalent to having three secondary coils, and is a great advantage.

A short secondary wire gives a current of low pressure but of large quantity, and as it suffers little by diffusion in the tissues, it is very useful to reach deeply-seated organs. The long secondary winding, on the other hand, gives a very small current but a high pressure or electromotive force. It suffers a greater proportionate loss by diffusion, and consequently its effects are more or less limited to the skin and superficial muscles.

In choosing a coil, always have it put in action, and carefully observe the working of the interrupter. It should work smoothly for ten or fifteen minutes at a time without adjustment, and should not be too noisy. The iron core and the sliding secondary coil should work smoothly, though not *too* easily, so that regulation can be effected without any sudden jumps.

Unfortunately, we have no reliable instrument, fit for everyday use, for measuring induction-coil currents, and we are compelled to employ our own or the patient's sensations as a guide to dosage. In a coil of the kind recommended, both the iron core and the sliding secondary coil are provided with a scale, by which can be read off the relative position of each to the primary coil. By always using the same apparatus, under approximately the same conditions, and observing the adjustments found most suitable, it soon becomes easy to judge with some accuracy the strength of the current that is being applied. A full description of the induction coil and the principles involved in its action will be found in any of the larger text-books on medical electricity.

Conducting Cords should be made of insulated flexible copper wire or tinsel, and

provided with suitable tips for securing to the battery terminals and electrodes. These tips are easily obtained, and with a supply of ordinary electric light "flexible," one can easily make one's own cords of any length required—from $1\frac{1}{2}$ to 2 yards will be found very convenient. A spare set should always be kept ready. They are liable, after being in use for some time, to break inside the covering, especially near the ends. In case of failure at any time, it is as well to make sure the fault is not in the cords before obtaining skilled assistance. It is a good plan to use cords of different colours, such as red and green, and always to attach the red one to the positive terminal.

Electrodes are plates of various sizes and shapes, made of some conducting material, and are the means by which the electric current is brought into contact with the patient's body. They are made most frequently of metal, such as lead; tin, or pewter, but may be made of carbon. Electrodes must always be covered with some absorbent material, such as flannel or wash-leather, which can be soaked in water—bare metal should never be used in contact with the skin when making electrical applications, except in very special circumstances. It causes pain at the time, and, later, burns or blisters at the point of contact, by virtue of the electrolytic products set free in the skin.

In most electrical applications, one pole is applied to the affected part—the *active electrode*; while the other pole is applied with a larger plate placed in some other part of the body—this is called the *indifferent electrode*.

Indifferent electrodes are generally of large size—from 12 square inches to 100 square inches or more. They are made of metal sheet about $\frac{1}{16}$ of an inch thick, and cut to any shape and size required. A terminal is soldered on to the back, to which the conducting wire is attached, and the whole is enclosed in a bag, one side of which is made of flannel or wash-leather, and the back of American cloth. When the front is soaked in water, the back may be dried and slipped under the patient's clothes without wetting the latter. It should be bent to fit the contour of the part as nearly as possible, and kept in place by firm pressure.

Owing to the difficulty of keeping this large electrode in proper contact, other devices are resorted to. The "chain-mail" electrode is now much used, since it admits of perfect adaptation; but one of the best available is a small bag made of cotton and metal strands, in which the hand is inserted, and used by scullery maids for cleaning pots and pans. They can be obtained from most dealers in kitchen requisites for a few shillings per dozen, and make the cheapest and most satisfactory electrodes.

Warm water has many advantages, and it is usually not difficult to apply. All that is required is a foot-bath, or other basin, in which the feet or the forearms or hands can be immersed. The electrode is hung over the edge so as to dip well into the water, and the parts are immersed. The water constitutes a perfectly fitting electrode, and the warmth, as well as the thorough moistening of the skin, reduce the resistance of the latter, so that large currents can be applied without the least fear of doing any damage. The only difficulty about a water-electrode is that the current tends to flow in mainly at the surface of the liquid, and some irritation is caused owing to the current density at this point.

Active electrodes are of small size, and circular metal discs, covered with flannel or wash-leather, are the most generally useful. A set of four, from $\frac{1}{2}$ in. to 3 in. in diameter, will meet most requirements. They are made to screw on to a terminal, which is mounted on the end of a handle of wood or ebonite. This makes them very convenient to use, and the operator is insulated from the circuit. For purposes of treatment, plain handles are all that is required. Some are made with a key for opening or closing the circuit. They are used for testing purposes, and occasionally in treatment.

One good form of disc is made with a rim turned back from the face, and provided with a celluloid ring a little larger in size. A piece of flannel or wash-leather is placed over the disc, and the ring pushed over both, holding the cover firmly in place. The superfluous material is trimmed off with scissors. Re-covering a disc is a matter of a few seconds, so that there is no excuse for using a cover more than once.

It should be an invariable rule to use a new cover, clean towel, and warm water for each patient and each application.

We will now proceed to study the character of the currents obtainable from our combined battery. These are three: the constant or continuous current, and the two induction coil currents.

II.—THE CONSTANT OR CONTINUOUS CURRENT.

The constant current is the current we obtain from chemical action such as takes place in a battery cell. In a closed circuit it flows evenly and steadily, always in one direction, from the positive to the negative pole, and on this account it is possible and easy to measure this current with the greatest accuracy. This is the current supplied by the *cells* of the combined battery. It is regulated by putting more or fewer cells in circuit by means of the crank of the cell collector, and the entire current passes through the

galvanometer or milliamperèmeter, before reaching the patient, the dose being thus accurately measured.

The action of the constant current is best studied by observing the effects at the two poles. At one time, a certain amount of importance was attached to the direction of the flow of current, and *ascending* and *descending* currents were spoken of. Further observation has failed to detect any special effect possessed by either of them in the interpolar area. The effects produced at the polar areas are distinct and characteristic, so that we now speak of the application of the anode (positive) or kathode (negative), as the case may be, and not of treatment by ascending or descending currents.

Before describing the effects observed at the two poles, it may be pointed out that, to produce any appreciable and more or less lasting effects at any place or part of the body, it is necessary that the *current density* be not less than a certain amount.

By current density we mean the number of milliampères of current passing per square inch (or centimetre) of electrode in contact with the body.

The exact density below which nothing takes place, and above which definite effects are produced, is not known, and probably would be found to differ in different individuals. Using an electrode of 1 square inch, a current of 0.1 milliampère would produce negligible results, while one of 10 milliampères would very soon produce evidence of its presence. The proper density to employ varies with the effects it is desired to produce. Speaking generally, current densities below 1 milliampère per square inch are of very limited therapeutic value. Except where we wish to produce destruction of tissue by electrolysis, the current density should never be so great as to cause actual pain at the seat of application, and in most instances the sensations of the patient will prove a fairly reliable guide. It will be found that when the electrode is kept on one spot (*stable*), the density must be less than when it is moved about (*labile*) over a greater or less area. By constantly watching the galvanometer in the case of the constant current, and the adjustment of the iron core or secondary coil of the induction apparatus, one soon learns the strength of current that may be employed with safety and a reasonable prospect of achieving the desired result.

In most cases the current is applied of such strength as to come short of real discomfort, and the duration of the application may vary from five minutes to half an hour or more.

In applying electrical currents to the human body, it is important to bear in mind that we are dealing with what is essentially a membranous bag filled with saline solution and tissues of varying consistency—and when we pass a constant, or at least a unidirectional, current through it, all the phenomena of an electrolytic cell are present. Strictly speaking, the case is not quite so simple as this, owing to the presence of fluids moving more or less rapidly along well-defined channels, or percolating through the intercellular spaces. Treatment by the constant current is essentially a transference of *ions*, of which we shall have more to say presently. The body offers considerable resistance to the passage of the current, and this is found to be due almost entirely to the resistance of the skin itself. The resistance of the subcutaneous tissues is so low by comparison that it may be neglected for all practical purposes.

The total resistance offered by any individual will depend chiefly on the state of the skin. A thick, dry, and cold skin offers the greatest, while a thin, moist, and warm skin offers the least, resistance. The advantage of freely using warm water, and electrodes covered with material which can absorb water readily, is easily seen. A further reason for so doing is that the electrolytic products which are set free in the immediate vicinity of the poles are absorbed by, and diluted with, the water in the electrode cover. These products are chemical compounds which irritate and even burn or blister the skin where concentrated, and by keeping a well-moistened medium between the electrode and the surface of the skin, the latter is protected from their action. The resistance further depends on the size of the electrode—the larger and the more perfectly the latter is applied, the lower the resistance will be—and finally, the longer the current is flowing, up to a certain point, the lower the resistance becomes. This is due to the gradually increasing vascularity and moisture of the skin under the electrode.

When a current of electricity is given more than one path, it divides itself between them, the amount going by each channel being in inverse proportion

to its resistance. If we place the two electrodes upon the surface of the body, the latter being a conductor, innumerable paths are open to it, but most of the current will travel by the most direct, or path of least resistance, and here the density of current will be greatest.

If we imagine the current to be made up of a number of thin lines or strands, where the density is greatest the strands are gathered together as in a cord. Where the density is less, it would resemble a cord more or less frayed out, though the same number of strands would be present. While some of the lines will take a very circuitous route in their journey from the anode to the kathode, all will be finally gathered in at the latter pole. It may be safely stated that, with the currents used in medical electricity, the current density in the outlying regions away from the direct line between the electrodes is so slight as to be of no practical importance.

If the two electrodes are placed close together, practically the whole current travels through the tissues immediately beneath the skin. If we move them farther apart, there is more diffusion, and the area of greatest density becomes less superficial. Consequently, if we wish to influence deep-seated structures, large electrodes are to be used, and they must be placed some distance apart.

If a small superficial area is to be treated, such as a case of neuralgia of a superficial nerve, a small electrode—usually the anode—is placed over the painful spot, while a large electrode is placed elsewhere. In this way the current density at the small or active electrode can be adjusted and produce definite effects, while no appreciable changes occur at the larger or indifferent electrode, because the same amount of current is spread over an area which may be from twenty to fifty times greater, and the current density proportionately reduced.

When we study the local action of the poles, we find that they differ from each other very greatly.

The Anode is the anæsthetic or sedative pole. Moderate currents have a drying, depleting, and hæmostatic effect on the surrounding area. Certain medical substances, chiefly bases, are diffused through the body by means of this pole. Strong currents cause destruction of tissue, though less than the kathode; acids—chiefly hydrochloric—and oxygen gas are liberated.

The Kathode is the stimulant pole. Moderate currents cause increase of moisture and quicken absorption. Blood-vessels and canals are dilated, acid radicles are diffused through the tissues. Strong currents are more destructive electrolytically than the anode, alkalies—chiefly caustic soda—and hydrogen gas being set free.

It is a help, to avoid confusing the two, to think of the positive pole as the “acid, anæsthetic anode.” This gives the reaction of the electrolytic product, and the chief effect of the anode when used locally. The properties of the kathode are the reverse of these.

Electrotonus.—When a constant or battery current is caused to traverse a nerve, certain changes are produced in its conductivity and irritability, especially in the immediate vicinity of the electrodes. The changes which take place at the anode—*anelectrotonus*—are not the same as those at the kathode—*kathoelectrotonus*. At the anode, the irritability and the conductivity of the nerve for nervous impulses are both diminished. At the kathode there is an increase of irritability, which rises suddenly at closure and acts as a stimulus to the nerve. In either case there is a gradual return to normal after the current ceases to flow.

All the above facts relating to the poles refer to the use of the constant current only, and are of great importance in guiding us in treatment.

We may here refer to what is known as *kataphoresis*. This refers to the movement of electrolytic solutions in the direction of flow of current, which

can take place through membrane or any porous diaphragm against the force of gravity. It is sometimes called *electric osmosis*, and when applied in medicine it is now known as :—

Ionic Medication.—This method is an application of the principles underlying electrolysis to the local administration of chemical substances to diseased areas. Substances which when dissolved in water are conductors of electricity, are called electrolytes, and in such a solution the molecules become separated and undergo dissociation. Sodium chloride, for instance, breaks up into sodium and chlorine, but each sodium atom is accompanied by its chlorine atom. These are called *ions*, and they carry definite charges of electricity. In the case of metals and some alkaloids the charge is a positive one, while the non-metals carry negative charges. It is the presence of this electrical charge that prevents the element appearing in its ordinary form, and in a solution such as we are considering the positive and negative charges are equally balanced.

If we place electrodes in this solution and pass a constant current, we upset this electrical balance, and the elements are deposited on the electrodes in their ordinary form. The ions of the metals carry positive charges and move with the current ; the ions of the non-metals carry negative charges and move against the current. This may be represented graphically :—

Here the sodium ions have moved with the current and accumulated at the negative pole, while the chlorine ions have moved against the current and arranged themselves at the positive pole ; and this takes place in spite of the presence of a membranous partition being interposed. This is what occurs during every application of the constant current, and is largely responsible for the effects produced.

Now suppose we wish to introduce the ions of iodine into a part with the idea of causing absorption of some inflammatory thickening, thus :—

Here we see that the normal constituents of the part have been replaced to some extent by the ions of the electrodes, and it will be easily understood how advantageous such a method is in some conditions, especially where we have a local disorder to deal with. It certainly is more scientific than to administer a drug by the mouth on the off chance that some of it may find its way to the particular spot we may be concerned about. The successful practice of ionic medication requires very careful attention to detail at every point. The chemicals, the water, and the lint pads, which must be of from eight to twelve thicknesses, must all be of the highest purity. Where possible, the metal of the electrode and of the electrolytic solution should be the same ; but if this is impracticable, extra thicknesses of lint must be used to prevent the ions of the metal electrode

reaching the skin. The present tendency in this class of work is to use large electrodes, large currents, and for considerable periods. Under such conditions an application of 100 milliamperes for an hour is not at all uncommon. While such procedure would be very hard on a portable battery, most ionic medication is done with much smaller currents and quite within its range. It will be as well to point out that metallic ions do not penetrate very deeply, owing to their property of forming a layer of albuminate next the electrode, which acts as a more or less impenetrable screen; at the same time they do go in far enough for many of the purposes for which we may want to use them. The copper ion has been found most useful in sterilizing the female organs of generation, and thus curing many conditions due to septic organisms that are most difficult to destroy in any ordinary way. For the treatment of rheumatic and rheumatoid conditions, a favourite method is to use a solution of the iodide of lithium for both electrodes. The lithium goes in from the positive, and the iodine from the negative, pole. For rodent ulcer or any septic ulcer, probably no ion acts so well as that of zinc: a superficial rodent ulcer is easily removed by a single application, but if it has begun to extend deeply, there is risk of recurrence. Once the principles of ionic medication are fully grasped, numerous indications will be found for it, and there should be no special difficulty in carrying it out properly.

For the relief of pain, such as neuralgia, the most generally useful ion is that of salicin, by using a solution of sodium salicylate under the negative pole; in some cases quinine answers well, but of course this must be applied under the positive pole, since alkaloids behave the same as metals. This has the further advantage that the positive pole of itself has a soothing action. The disadvantage of quinine is that it is difficult to get a satisfactory neutral solution, but a solution of the salicylate might give good results if carefully and scientifically prepared. Speaking generally, all solutions used in this class of work are of about 2 per cent strength.

III.—THE INDUCTION-COIL CURRENTS.

They are two in number: (a) The primary current, or current of self-induction; and (b) The secondary induced current.

a. *The Primary or "Self-induction" Current* is obtained when we attach our electrodes to the beginning and end of the primary coil winding. The current being turned on and the vibrator set going, with each movement of the latter we are conscious of a distinct shock, the strength of which depends for the most part on how far the iron core is inserted into the coil. For this current to be perceptible, it is necessary that the primary coil be composed of at least one hundred turns of wire, and most coils have many more than this. The self-induction current is in the same direction as the battery current, and is caused by the inductive influence of each turn on the other turns adjoining. It manifests itself at the moment the vibrating spring leaves the contact screw.

On most coils, near the contact-breaker, a small single-arm, two-way switch is provided, with its contacts marked P and S respectively. When the arm is moved to the side marked P, it means we are getting this self-induction current at the terminals to which the conducting cords are attached. The essential feature of this current is that it is composed of short unidirectional waves, between which there is a definite interval. The strength or volume of the current is not large, and it is never reversed in direction—it is an intermittent or pulsating current.

If we insert the iron core, the waves follow one another more slowly, and the strength of current is increased. In beginning any application with the induction coil, the iron core should first be withdrawn to its fullest extent. It is then gradually inserted as the application proceeds, until the proper strength is attained.

In many induction coils, the iron core is fixed in the centre of the primary coil. In such a case, regulation is effected by sliding a metal tube over the core. Its effect is to screen the primary winding from the inductive influence of the iron, and has the same effect as withdrawing the latter. In a coil of this kind the tube is pushed in to its fullest extent at the commencement of the application, and gradually *withdrawn* till the current is sufficiently strong, the movements being the opposite of the movable iron core.

In portable coils such as we are considering, owing to their necessarily small size the volume of current is small, and it is a very pleasant one for both testing and treatment so far as it goes. Large primary coils have been made, chiefly for bath purposes, when a large volume of current is desired, but they are being displaced by the sinusoidal current, which is more pleasant for the patient and more effectual in action. The sinusoidal current can be obtained only from the alternating current main, or from a small dynamo installed for the purpose. Therapeutically, it is one of the most valuable currents we possess.

b. The Secondary Induced Current.—If we now move the switch already referred to to the side marked S, we get the "secondary induced current." This comes from the secondary coil, which is not connected directly to the primary coil in any way, but is wound on a bobbin, the hole through the centre of which is large enough to allow it to slide over the primary. By so doing, the secondary is brought more or less into the magnetic field set up by the primary coil, and the electromotive forces in it are thereby adjusted. The secondary coil has from five to fifteen times the number of turns of wire as the primary. The effect of the large number of turns is to give sufficient electromotive force at "make" to produce a perceptible current; at the same time the impedance of this large number of turns prevents the current at "break" rising to a proportionate degree, though it still exceeds the current at "make." The result is, we get a current alternating in direction but not symmetrical.

By inserting the iron core these waves are prolonged and made less symmetrical than before. Also the strength of the current is increased, and it is less agreeable to the patient.

In using this current the iron core is first withdrawn—or the metal tube pushed over it, as the case may be—and the secondary coil is moved clear of the primary. The electrodes being in position, the secondary is pushed gradually over the primary until the desired strength is reached. If insufficient when pushed right home, then the iron core is inserted.

It will be seen that the feature common to both these coil currents is that they are constantly varying in a more or less regular manner. They differ from one another in that the primary or self-induction current is always flowing in the same direction, while the secondary current is an alternating one. The alternate waves of the latter are, however, not of equal magnitude.

In either case, the strength or amount of current flowing is very small, and while with the primary current there may be some slight chemical action on the tissues, we may say that, for all practical purposes, the chemical and electrolytic effects of both coil currents are negligible.

The chief value of induction-coil currents depends on their stimulating action on living tissues. All tissues and cells are influenced more or less, that of muscle being the most obvious and easily demonstrated. They act as a tonic, which may be local or general, according as the method of application employed is local or general. If the patient be put in a bath and the current passed through, it acts in many instances as a most efficient tonic, and is most useful in anæmia, debility, delayed convalescence, etc. The same method may be employed locally, in the treatment of atrophied and paralyzed muscles, and in faulty local circulation. Their action is considerably modified according to the rapidity of the interruptions. These, when slow, produce more painful and powerful contractions than when fast. If the rapidity is very high, anæsthesia can be produced.

IV.—ELECTRO-SURGERY.

Those surgical applications of electricity which can be carried out with the combined portable battery as the only source of energy, are not very numerous. It is not wise to use such a battery for treating a large nævus, for instance. The large current required would quickly exhaust the small cells composing it, and the current might fail for this reason before the operation was completed. There are certain cases, however, occasionally met with in general practice, which can be dealt with quite satisfactorily, and the operations are easy to perform.

Removal of Superfluous Hairs.—For this, a good light is essential. The indifferent electrode—anode—is bandaged to the forearm. The other pole is

connected to a fine platinum needle, mounted in a handle to which the conducting cord is attached. Each hair has to be treated separately, and when a large surface has to be done, it is better to remove hairs from every part, and not from one spot. About twenty is the largest number that can be treated at a single sitting, and if these were removed from one spot, a troublesome ulcer would very likely result.

Besides the epilation needle a pair of forceps is required (*Fig. 27*), and four cells are placed in circuit. The hair is grasped by the forceps, and gentle traction made in its normal direction. The needle is then introduced into the follicle alongside the hair for a distance of about $\frac{1}{8}$ inch. In a few seconds a slight effervescence is seen at the orifice, and the needle is withdrawn. The hair should come out very easily; if not, the needle may be inserted again, perhaps a little deeper, for a couple of seconds.

The success of this little operation requires practice, patience, and skill. The needle should not be too sharp; a rather dull point finds its way along the follicle more surely and easily. Platinum or platinum-iridium needles should always be employed, and should be sterilized in the flame of a spirit-lamp before use. There is a stinging pain while the needle is in the follicle, but it is never so severe as to require a local or general anæsthetic. Under the most favourable conditions a few of the hairs return, and have to be removed at a future time.

Fig. 27.—Epilation Needle and Forceps (Schall).

Moles.—These, when occurring on the face, constitute a disfigurement which the possessors are usually glad enough to be rid of, if it can be done easily and without severe pain. If small in size and hairy, epilation as above may be all that is necessary. After the hairs are removed, the pigmentation disappears to a large extent, if not altogether, and the mole shrinks in size. If large

and highly pigmented, it had better be treated as an ordinary nevus.

Nævi.—These are sometimes met with in general practice, especially in infants, and when under an inch in diameter can be successfully treated with small battery cells. Such work tends to exhaust the latter rather rapidly, but it is generally worth doing, and the cells are easily replaced. The object is to break up the blood-vessels and coagulate the blood therein, without causing general necrosis of the mass, and consequent sloughing. It is important to know when to stop. If the growth is subcutaneous, the skin is not to be interfered with, except for the minute openings where the needles are inserted; but if the skin also is involved in the growth, some scarring is unavoidable. The pain is severe, and an anæsthetic is always necessary with children, and also in many cases occurring in adults.

For very small nævi, or prominent blood-vessels in the skin of the face, the epilation needle and pad, as used for the removal of superfluous hairs, are all that is necessary. If desired, a somewhat stouter needle may be employed with advantage. When using a single needle as the active electrode, it must always be the kathode if the best results are to be obtained.

Occasionally nævi of a stellate form are met with, where all the vessels composing it seem to radiate from a common point. If the needle is inserted at this point for a few minutes, the whole will probably disappear. The indifferent electrode is placed on the sternum or other convenient part, and from four to six cells are put into circuit. The needle is then gently pressed in at the desired place, and soon dissolves its way through. The current in such cases should not exceed 10 milliamperes, and probably half that amount will be sufficient. It should be kept in place until the dark discoloured area surrounding the needle where it has entered the skin is about $\frac{1}{8}$ inch in diameter. When finished, the cells should be very slowly cut out one by one, and the needle withdrawn.

For anything over $\frac{1}{4}$ inch in diameter, and especially if it is thick as well, it will be found more satisfactory to employ the bipolar method. For this we require the special bipolar needle devised by Dr. Lewis Jones (*Fig. 28*). In this, the two wires from the battery are joined to the two terminals on the holder, and the internal connections are such that the needles are positive and negative alternately. Two, three, four, or five needles may be employed, according to the size of the mass to be treated. Three are about as many as can be used when working from the cells of a portable battery.

From four to six cells are put in circuit, and the needles pushed into the mass. To be quite safe, the current should not exceed 20 milliamperes per inch of *positive* needle.

Soon after the needles are inserted the tissues around them begin to change colour. At the positive needle there are hardening and pallor, and the needle itself tends to become fixed and difficult to withdraw. Round the negative there is frothing from evolution of hydrogen gas, and the needle gets quite loose. The tissues become dark, livid, and boggy, and when this occurs the needles should be partially withdrawn, and re-inserted in different directions from time to time, until the whole mass is broken up, and the blood in the vessels more or less completely coagulated. The aim should be to destroy the growth as far as possible at the first operation. This is easy enough when the nævus is not more than $\frac{1}{4}$ inch in diameter. If larger than this, two or more operations will be necessary.

Fig. 28.—Bipolar Needle-holder (Schall).

The after-treatment is quite simple. In most cases a piece of antiseptic gauze is secured over the punctures by means of flexible collodion. If sloughing should occur, an antiseptic poultice is applied until the slough separates, and the ulcer is treated on general principles.

It should be remembered that the treatment of large nævi requires currents which will exhaust small dry cells very quickly, so that the cells so used may have to be renewed before the rest of the battery is used up. For treating these large nævi it is better to use a battery of large cells; but the method is described here, since it is possible to use the smaller cells found in portable batteries.

The treatment of *aneurysm* and *strictures* by electrolysis is beyond the scope of this article, and will be found fully described in the standard works on medical electricity.

The electric cautery is of course not an instrument for electric treatment. The part played by electricity is merely that of a convenient means of heating the burner. The large currents required for this purpose are far beyond the capacity of a battery such as we are treating of.

V.—GENERAL ELECTROTHERAPEUTICS.

Rockwell, in his excellent book, describes the action of electricity in the treatment of disease as a stimulating, sedative tonic. It is important to remember that electricity is not a stimulant in the ordinary sense of the term—that is to say, an agent which will temporarily rouse the system quickly to increased activity. Surprisingly rapid results may sometimes be obtained from a local application in certain cases, but the effects of electrical treatment do not appear so rapidly as a rule. Like other tonics and alteratives, its effects are produced gradually, but it differs from them in possessing valuable properties peculiar to itself. It is a stimulant, in that it corrects and intensifies or economizes the forces of the system; a sedative, because it tends to relieve irritability and pain, and encourages natural repose. It is a tonic, because it improves nutrition, restores enfeebled functions, and so improves the capacity of the system for labour.

Electricity acts as a stimulus to nervous structures, through which the vasomotor system and all the tissues are brought under its favourable influence. This is shown in the treatment of general debilitated conditions such as anæmia and rickets. After a course of some form of general electrization, these conditions are very often improved in a remarkable manner—sleep, digestion, and general appearance being greatly benefited.

Locally, electricity is of the greatest value in cases of injured or diseased nerves, atrophied and paralyzed muscles, in the removal of inflammatory products, and the relief of pain. The particular form of electricity used will depend on the nature of the condition we wish to treat and the particular effects desired. If we want the stimulating effect, we shall employ a rapidly varying current, and this is obtainable from the induction coil. As a sedative, the constant current is used, always placing the anode over the seat of pain, and employing a relatively high current density.

For treating deeply seated organs with the coil, it is best to set the interrupter to work as slowly as possible, and have the electrodes far apart. If the constant current is preferred for any reason, one electrode should be kept slowly moving to and fro over the affected area.

Dosage.—It should be an invariable rule in electrical treatment never to turn the current on or off suddenly. Anything which would cause a sudden variation in the magnitude of the current flowing will produce a shock, especially with the constant current. Apparatus of this kind should be most carefully made, and kept in perfect order. A loose connection, for instance, may give rise to severe shocks if the battery receives a knock or jar during the application of strong currents. If the head or neck formed part of the circuit at such a time, the most serious or even fatal results might occur. Here it may be as well to say a word to the wise. Apart from any question of danger, many patients are extremely intolerant of even the slightest shocks, and carelessness in this respect will inevitably lose the confidence of the patient, which means the loss of the patient as well. The strength of current for local applications varies from 5 to 10 milliampères as a rule. In certain cases much larger currents are employed.

From ten to fifteen minutes is usually long enough for each application, and they may be repeated two or three times a week under ordinary conditions. Treatment should in most cases be persisted in for at least one month, when it will be possible to judge of the value of the method in any given case.

Mode of Application.—While under certain special conditions special electrodes are used, the great majority of electrical applications are made with ordinary electrodes. The indifferent electrode, whatever form it takes, is first adjusted. Where metal plates are used, they should be faced with from six

to twelve thicknesses of ordinary lint that has been well moistened with warm water, and care must be taken to see that they are properly adapted to the contour of the part. The active electrode is then applied to the part it is desired to treat, and the current gradually turned on. Always begin an electrical application with the adjustments at zero. The active electrode is kept in one place—*stabile* method—or moved about over the affected area—*labile* method—according to the requirements of the case. For instance, in treating facial neuralgia, the active electrode would be the anode used *stabile*; while for a case of facial paralysis we would employ the kathode *labile*—the effect of the latter method being, so far as any particular part of the area is concerned, that of a slowly but constantly varying current. In all circumstances keep the electrodes well wetted, particularly when used *labile*; a little soap on the surface is an advantage.

If muscular contractions are desired, the current may be interrupted by means of a key in the handle, or it may be reversed with the reversing switch of the battery. The latter is the more powerful, and is particularly useful in stimulating unstriated muscle.

It has already been stated that water forms a most valuable medium through which to apply electricity, and it will be found that there are few instances where it cannot be made use of with advantage, more often as a large, perfectly fitting, indifferent electrode, but sometimes as an active electrode as well. Arm and leg baths of paper, pulp, or earthenware are easily obtainable. The current is brought to the water by means of a strip or plate of metal hung over the side so as to dip well into the water, but away from the part of the body immersed. These plates are provided with a binding screw, to which the wire from the battery is attached. Where only one plate is immersed, the arrangement is called the *monopolar bath*, which is largely used in hospital practice. If both electrodes are put in one bath or trough, we have what is called the *dipolar bath*. This latter may be of such a size as to treat one limb only, such as the forearm or hand, or it may be large enough to take in the whole body.

One advantage of the *monopolar bath* is, that all the current flowing through passes also through the patient, so that we know exactly the dose the latter is getting. With the *dipolar arrangement*, part of the current passes through the water without touching the patient, so that the dose is more a matter of guess-work.

It is seldom, if ever, necessary to add salt or other substances to the water to increase its conductivity. It may be an advantage sometimes in the *monopolar bath*, if the battery power available is weak, but it must not be done in the *dipolar arrangement*. The success of this depends on the resistance of the water being greater than that of the patient, and if we reduce the resistance of the former, the result is to allow more current to pass around the patient, and so use up our battery to no purpose. A course of galvanic full baths is rather beyond the scope of a portable battery, but it may be used for the *faradic bath* if desired—the cells supplying the latter being larger in size, and the drain on them not so severe.

A full description of the electric bath is beyond the scope of this article; a book on medical electricity should be referred to for information on the subject. As a means of “general electrization,” it is probably the most valuable, and the one most often employed in this country.

General Electrization.—This term is applied to any method which has for its object the placing of the whole body under the influence of electricity in one or other of its forms. It may be carried out in several ways, such as by the use of static electricity, high-frequency currents, and by any one of the currents employed in the *hydro-electric bath*—*faradic*, *galvanic*, or *sinusoidal*. Practically

all of these are beyond the scope of a portable combined battery, the one exception being the faradic bath, which has been referred to already. Modification of this latter is known as "general faradization," and is one that can be carried out very efficiently by any good portable battery containing an induction coil. It is a very popular method in America, and is much practised by specialists there. In the United Kingdom the most popular form is the sinusoidal bath, thus indicating a striking difference in the general practice of the two countries.

General Faradization is carried out as follows. The patient stands or sits on a large metal plate, which is covered by moist flannel, and if necessary kept warm by a hot-water bottle. One of the conducting cords from the coil is attached to this plate, and the other cord to the active electrode, which may be one of the ordinary circular discs, covered and wetted in the usual way. This latter is sometimes held by the operator in one hand, while he uses his other hand as the active electrode. It is worked over the head, neck, back, abdomen, arms, and legs, in this order, giving from two to four or five minutes to each. It is not necessary to remove the underclothing, and the current should not be so strong as to give discomfort to the patient. The immediate effect is a comfortable sense of well-being, with relief of fatigue. With a course of this treatment, both appetite and sleep improve, and there is a general return to normal condition. It acts truly as a stimulating, sedative tonic, and is indicated in all those disorders which experience has shown to be benefited by an agent of this kind.

A recent modification of general faradization has been introduced by Bergonié for the treatment of obesity. The subject reclines on a set of electrodes attached to a chair, while other electrodes are placed over and held in position with sand-bags—the latter also acting as a load for the muscles to work against. Current impulses pass between the electrodes in such a way as to cause the principal muscles to contract rhythmically and in regular order. The result is that the patient performs a large amount of work without mental and with little bodily fatigue. Weight is rapidly reduced, and so far the results have been very satisfactory. Necessarily the apparatus is both costly and extensive, and the method scarcely comes within the province of the general practitioner. It is free from most of the dangers that occasionally follow the use of drugs and vigorous dieting; the treatment can be obtained at some watering-places, such as Harrogate and Bath.

Central Galvanization is also a favourite mode of electrical application in America. The object is to bring the whole central nervous system—the brain, cord, sympathetic, and vagus—under the influence of the constant or galvanic current. One pole—usually the negative—is placed at the epigastrium, while the other is passed over the forehead and vertex, along the inner border of the sternomastoid muscle, and along the whole length of the spine.

In applying the current to the head, it must be turned on and off while the electrode is in position, and the application may be from two to three minutes. The hair must be well wetted before placing the electrode over the vertex.

The duration of the application along the border of the sternomastoid may be from one to five minutes each side, about three minutes to the nape of the neck, and five minutes along the rest of the spine. The strength of the current to the head will be from 5 to 10 milliampères, and to the spine from 10 to 30.

This method is useful in those diseases which would seem to be due to a state of exhaustion and irritability of the central nervous system, such as hysteria, chorea, neurasthenia, epilepsy, neuralgia, and even some forms of insanity. It has not been employed very much in this country, but it is certainly worthy of further trial.

It will be seen that with only a portable battery at our disposal, some of the chief modes of applying electricity to the body as a whole can be carried out

quite as efficiently as with more elaborate apparatus. They can always be tried with a reasonable prospect of success in cases where they would seem to be indicated. When they fail, it will be time enough to refer the case to the electromedical specialist.

High-frequency Currents.—This form of electrical application is one that is used only by those who specialize in electrical treatment. The apparatus required is bulky and expensive, and as a rule quite outside the province of the general practitioner, but a brief account of the nature of the method, and indications for its use, may be of service.

Apparatus for the production of high-frequency electrical currents is of two kinds. The first and most common at present is that made to give out a high potential current of small volume or strength. The other class, only recently introduced, is made to generate a low potential current of large volume, and its effects are entirely thermic; heat can be applied to the issues through the passage of the large volume of current sufficient to cause charring or any degree short of it. This has been called "thermopenetration," or "diathermy."

The principles underlying the production of these currents are the same in both cases. To begin with, a current of high potential is necessary, which is most commonly obtained from an induction coil such as is used for x-ray purposes. The wires from this are led to the inner coatings of two Leyden jars (one wire to each), arranged side by side. Connected to these two wires is a spark-gap, across which the jars may discharge after they have become charged to a sufficiently high potential, which depends upon the distance separating the two points of the spark-gap. The discharge of the jars is accompanied by a very disagreeable noise, and therefore the spark-gap is always enclosed in a glass box. It has been found that the discharge of a Leyden jar, instead of being the single spark it appears, consists of an enormous number of oscillations, the frequency of which may under certain conditions amount to a million or more per second. The charge of the coating of the jar is altered with each oscillation, and as corresponding charges are induced in the outer coatings of the jars, high-frequency oscillations are obtained if these outer coatings are joined with a conductor; and if this conductor is made of coarse copper wire formed into a spiral, it will offer considerable resistance to a high-frequency current, owing to the phenomena of self-induction.

By connecting wires to the copper spiral, as much current as is required, up to the capacity of the instrument, can be drawn off—the greater the number of turns of the spiral between the points of connection of the two wires, the greater the amount of current drawn off. This is the method of obtaining this form of electricity for a general application, but sometimes the copper spiral is made large enough to enclose a couch upon which the patient lies. With the flow of high-frequency oscillations in the spiral, corresponding electrical oscillations are induced in the patient's body.

Another form more commonly used is to lay the patient upon a thick cushion under which is placed a sheet of metal. One end of the spiral on the machine is connected to this metal sheet, and the other is joined to the patient by ordinary handle electrodes. In either arrangement the patient's body becomes traversed by high-frequency currents, and if a bystander brings a finger close to any part of his body, sparks will pass between. It is curious that although the volume of current is so large, no sensation is felt beyond a little warmth at the electrodes, or sometimes all over the body.

If one end of the spiral on the machine be joined to a separate spiral, the potential of the current rises to such an extent that a profuse brush discharge is given off from the other end of this second spiral. The volume of current is not so great, but it is very useful as a local application—in fact, many

observers believe this to be the only really useful application of the current from the usual form of apparatus.

The local application of high-frequency electricity is carried out either with a plain metal point on the end of an insulating handle, or by means of glass electrodes filled with saline or other conducting solution, or partially exhausted and therefore conducting. In both cases the current acts inductively upon the body when placed in contact with, or close to, the outer surface of the electrode.

When the metal point is used, the latter is held a little distance from the surface to be treated; the farther away, the more severe the effect, until it is removed so far that no sparks pass.

The general influence of high-frequency electricity is not very pronounced. Some patients find that it acts as a stimulant, and it is frequently compared to the invigorating effect of a glass of champagne. Others, again, experience no such effect, and find it produces a tendency to sleep. It has been proved that a course of treatment increases metabolism, shown by an increase in the elimination of carbon dioxide and urea. It also causes a dilatation of the cutaneous capillaries, bringing about a lowering of the blood-pressure, and is thus indicated in arterial hypertension. That some patients find it of benefit when run down, and during convalescence, is undoubted, but its action is very uncertain. It is, after all, one form of general electrization, and is indicated as such. There is no evidence to show positively that it possesses any distinct advantage over other methods, such as a course of hydro-electric baths, general faradization, or static electricity; at the same time it may answer where other methods have failed. General applications are indicated in gout, diabetes, anæmia, general debility, and rheumatism. The local application is probably the more satisfactory. If the metallic brush electrode is used, it is held as close as possible to the skin without white sparks passing, unless it is desired to produce a severe effect. The brush discharge is at times useful in relieving the pain of neuralgia and of muscular rheumatism. When the electrode has but one point and is held close enough to allow of sparks passing, we have a mild form of what has been termed "fulguration." This, when applied to acne vulgaris, warts, psoriasis, eczema, obstinate ulcers, chilblains, alopecia areata, and allied conditions, gives excellent results in a large proportion of cases.

Some cases of the troublesome "port-wine stain" respond very well, but the sparking must be severe and the electrode held not too close. The application must be continued until the surface is blistered: the pain is intense, and in most cases a general anæsthetic will be necessary, but not ether, as the spark will easily ignite the vapour.

The indications for the use of the glass electrodes (or condenser electrodes as they are called) are essentially the same. The application is more comfortable to the patient, and they are probably the best to use for eczema, psoriasis, alopecia, and ulcers.

Recently, powerful apparatus has been brought out for very intense sparking of malignant growths. This is what is known as "fulguration," and has attracted considerable attention. It is mentioned here only to point out that experience has shown it must not be considered a cure for malignant disease.

We might mention that some observers have had good results in pruritus and in the early stages (only) of hæmorrhoids, from the use of the high-frequency vacuum electrode applied locally.

The apparatus employed for "diathermy" differs in no essential from the one just described, but has been modified to suit the conditions. It gives out a current of from 200 to 800 volts pressure, and a maximum of about $2\frac{1}{2}$ ampères.

A high potential current is of no use when it is to be applied to the body, on account of the low resistance of the latter.

The resistance of the skin to this form of current may be ignored; also the electrodes may be comparatively dry without ill-effect. This current will travel equally well along and across fibres, and its heating effects are confined to a straight line between the electrodes.

If we take a pair of disc electrodes, say one inch in diameter, connected to the machine, place between them a piece of ox liver of almost any thickness, and pass a current of about $1\frac{1}{2}$ ampères for a few seconds, we find that a core of tissue having a section equal to that of the electrodes has been coagulated by the intense heat generated within it by the passage of the current. Again, if we hold a pair of ordinary handles and turn on the current for a few seconds, we feel a very distinct internal heat, chiefly at the wrists and up the forearms.

If we place the electrodes on each side of any joint, the latter can be heated up internally, and this property has been found useful in the treatment of osteoarthritis, rheumatoid arthritis, gonorrhœal rheumatism, gouty tophus, pyorrhœa alveolaris, and the relief of pain. Diathermy has also given good results in local disorders of circulation, such as coldness of the extremities and chilblains; and in some forms of neuralgia, such as sciatica, it seems to answer better than ordinary electrical applications. It must be remembered that the method is not, strictly speaking, an electrical form of treatment. As in the electric cautery, the current is merely the means employed for producing the necessary heat. (See THERMOTHERAPY.)

More progress has been made with the surgical applications, it being an easier and more direct field to work in. This property of heating and coagulation may be put to a variety of uses. Small tumours, simple and malignant, may be destroyed *en masse*. No hæmorrhage ever occurs, and bone is as accessible to its action as are the soft tissues. Enlarged tonsils have been successfully dealt with, and it has been found most valuable in gynecological work, even to the extent of doing a complete hysterectomy, in the process of which the tissues are separated by a sort of "cold" cautery action with a special form of electrode. After coagulating a growth, a zone that has been strongly heated but not killed is seen just beyond the coagulation area. In this a strong reaction follows, with a profuse flow of lymph and the usual accompanying conditions. Good results have been obtained in the treatment of lupus vulgaris, but there is in this, as in other burning applications, a risk of keloid developing in the scar; therefore diathermy is not likely to come into favour for cosmetic surgery.

VI.—LOCAL ELECTROTHERAPEUTICS.

It is in special regions and localized conditions that the portable battery finds its greatest field of usefulness. For a local application of any kind, the total current permissible is quite within the capacity of this instrument. This, in fact, may be said to be the particular work for which it is designed.

Diseases of the Brain.—Electrical treatment here has been rather neglected of late years, partly because it was not believed to be capable of doing any good, and partly from a fear of unpleasant effects during the application. As a matter of fact, the application of electricity to the brain is, in skilled hands, unattended by either pain or discomfort, and in the constant current we have a powerful means of controlling the circulation within the skull. Induction-coil currents are of practically no use in cerebral conditions.

If we apply the constant current to the head, placing the kathode on the forehead and the anode on the nape of the neck, the flow of blood in the head is increased. This is indicated in combating the effects of mental overwork and for stimulating mental activity.

If, on the other hand, we wish to relieve congestion, the position of the electrodes is reversed. In all cases, the current must be turned on and off most gradually; the average dose will be about 5 milliamperes. It has been more or less successfully employed in **Mental Apathy** associated with, or preceding, insanity.

This application of the constant current to the head has been very successful in the treatment of several cases of intractable headache. In most of them the trouble seemed to be due to a congestive condition, and was relieved by making the current traverse the head from the forehead to the nape of the neck. In one or two cases where the cause was cerebral anæmia, the opposite arrangement of the poles gave better results.

The **Melancholia of Adolescents** has been greatly benefited by a course of sinusoidal baths, and no doubt a course of general faradization would do nearly the same amount of good. These cases are very often accompanied by a failure of general nutrition. By improving the latter, the brain benefits indirectly. (See also **MENTAL DISEASES**.)

Insomnia.—A tendency to fall asleep on the part of a patient undergoing some form of general electrization is a common occurrence, and it is only natural that it should be made use of in the effort to relieve this troublesome condition. General faradization, or the faradic full bath, should be tried. If the results are not entirely satisfactory, a course of sinusoidal baths, high-frequency, or static electricity, may be more useful. Most cases are influenced favourably by electrical treatment. (See also **INSOMNIA**.)

Exophthalmic Goitre.—The use of electricity here is quite empirical, but a considerable number of cases do very well. The method of procedure is essentially the same as has been described by some writers under the term "subaural galvanization," or "galvanization of the cervical sympathetic." The constant current is to be used; the anode—a large indifferent electrode—to be placed over the lower cervical and upper dorsal vertebrae, while the kathode is moved slowly up and down the anterior border of the sternomastoid muscle from the mastoid process to the clavicle. The current is from 2 to 3 milliamperes, and each side should be treated for six minutes, two or three times a day at first, and always when palpitation comes on. The patient should be instructed to carry out the treatment for herself, and it should be persisted in for at least two months. Small dry-cell batteries specially made for this purpose are now obtainable, and are quite inexpensive. (See also **GOITRE**, **EXOPHTHALMIC**, and **RADIOTHERAPEUTICS**.)

Hemiplegia.—Nothing in the way of electrical treatment should be attempted for quite a month from the onset. There is always a chance that some good may be done, particularly in the milder cases, and while complete restoration is impossible, a certain amount of improvement is the rule, and this the patient should have the benefit of.

Constant current is applied to the head—taking care to observe all the precautions necessary in such applications which have been stated already—in such a way as to bring the seat of the lesion into a straight line between the electrodes. The object of this is to improve the circulation, and also to promote the absorption and removal of effused products. For the limbs, the metallic brush is used to apply the coil current over anæsthetic areas. The full length of the secondary coil—or the fine wire secondary, where two are provided—is to be used, so as to attain the maximum of sensory effect. The paralyzed limbs are to be treated with the short, or coarse wire, secondary coil, and the current is best applied through the medium of water. Most cases are more or less benefited for a time, after which further improvement is impossible. (See also **HEMIPLEGIA**.)

Paralysis.—Probably no symptom is more often present than this, in the cases one is called upon to treat by electrical methods. In treating a case where it is present, we must attack every part that is in any way affected by the disease. The seat of the lesion causing the paralysis should be treated as indicated above for hemiplegia. The paralyzed muscles are also to receive applications of constant or coil currents, as may seem best to employ. Their nutrition is improved, and, the current acting on the sensory nerves, reflex impulses are sent along the nerve trunks to the affected muscles.

In treating paralyzed muscles, a general rule is to use the coil current if the muscle will contract to it, but if not, the constant current will be found preferable. As the muscle improves under this, the coil can be brought into use to complete the cure, as far as such a result is possible. A further point worthy of attention is, that the kathode, or stimulating pole, should be the active electrode in treating paralysis with the constant current, the anode being placed over the nerve trunk or cord, according to the seat of the lesion. All forms of electrical stimulation are of use in the treatment of paralytic conditions, and as the induction coil in some form is everywhere obtainable, there is no excuse for not using it.

An important aid to recovery is daily massage of the affected muscles. This should be done for about fifteen minutes, using a little vaseline or lanolin to lubricate the skin. Another matter to be attended to is that of warmth. Paralyzed limbs are nearly always cold, from poor local circulation, and they should have extra covering, especially in the cold weather, and it should be worn at night if necessary. The strict observance of all these details, which make for the good of both the local and general condition of the patient, is necessary in every case. Carelessness in these matters may make all the difference between partial or complete success and absolute failure.

Infantile Paralysis.—This is a condition for which much can be done by steady, persistent treatment. While the more severe cases will tax to the utmost the patience of all concerned, the result is nearly always worth striving for. Without electrical treatment the recovery is slower and less complete. In severe cases it is an advantage to use the constant current at first; but if this is not convenient, induction-coil currents will answer almost as well.

The method of application will vary with the seat of the paralysis. If in the legs, or even in one leg, they are immersed one in each of two basins or buckets, which have a metallic plate hung over the edge so as to dip into the water, connected to the terminals of the coil or battery. Or the child may be placed in a wooden or porcelain bath, in which is put enough warm water to cover the legs. In this case one electrode is placed at each end of the bath. The current is turned on very slowly, and must never be so strong as to make any muscles rigid. With fretful children, it is a good plan to arrange everything in the proper way, but not to turn on any current at all at the first sitting. By gradually increasing the strength at subsequent sittings, the desired end is attained.

Peripheral Nerves.—Electricity may be said to hold a recognized position in the treatment of those symptoms which result from injury or disease of the peripheral nervous system. In any such case, the condition to be treated may be stated in the general term neuritis, and the method of treatment will depend a great deal on the severity of the symptoms. If pain is a prominent feature, the constant current is indicated, using the positive pole, or anode, over the painful area. In the absence of pain, the coil may be used with good results. Whatever current is selected, it should be applied through the medium of water, where possible, and the water should always be as hot as the patient can bear with comfort. (See also NERVES, PERIPHERAL.)

Facial Paralysis is a very common form, in hospital practice at least, and fortunately is one that generally does well. One reason for this is, that patients will take more trouble about restoring the symmetry of the face than about any other part which did not cause obvious disfigurement.

The indifferent electrode—anode—is placed at the nape of the neck, while the kathode is moved about over the affected side. It should be remembered that the skin of the face is thin, and that the muscles are close to the surface; consequently strong currents are unnecessary and even undesirable. The principles underlying the treatment of any of the other forms of paralysis of peripheral origin are essentially the same, and need not be described in detail.

Neuralgia.—The electrical treatment of neuralgia follows one or other of two main principles: that of counter-irritation, and that of the production of a state of anelectrotonus in the painful area. If it be a referred pain, counter-irritation is indicated, the current being applied from a long fine-wire secondary with the metallic brush, with the surface of the skin quite dry. If the pain be due to a local neuritis, this method would probably make it worse. In such a case we must employ the constant current, placing the anode over the painful area and passing a relatively large current.

The method of dealing with a severe case of facial neuralgia will fairly indicate the course of procedure in any given case. An electrode of sheet lead is cut roughly to the shape of the letter E. From six to ten thicknesses of lint are cut to the same shape and well moistened. The upright part of the E is placed along the side of the face, while the horizontal parts are placed along the forehead, cheek, and chin respectively, the lint being, of course, between the metal and the skin, and the former is connected to the positive pole of the battery. The negative is connected to a plate which hangs in a foot-bath filled with warm water, in which the patient's feet are immersed. The current is to be turned on very gradually, until from 30 to 50 milliamperes are passing, and continued from twenty to thirty minutes. It is then turned off in the same gradual way, and the whole process repeated daily until the tendency to the paroxysms disappears.

In some cases it has been found advantageous to soak the lint with a 2 per cent solution of sodium salicylate and use the negative pole. The salicin is introduced locally, and has succeeded in cases which resisted all other methods. (See also NEURALGIA.)

Localized Inflammations.—In the later stages when there is slowness of recovery, with passive congestion and accumulation of inflammatory products, electricity in the form of the constant current acts very beneficially. In these cases we may with great advantage adopt the measures described under *Ionic medication*. In the case of stiffness of the ankle following injury, we should take several strips of lint soaked in a 1 per cent solution of potassium iodide, and wrap it around the joint many times so as to get several thicknesses over it—the more the better. Over this are wrapped some strips of tea lead, which overlap each other freely, so as to make a well-fitting electrode, to which is attached a wire from the negative pole of the battery, the whole to be firmly secured with an evenly applied bandage. For the indifferent electrode, the sound foot and leg may be immersed in a bucket of warm water containing a plate of metal connected to the anode. In such a case a current of about 20 milliamperes may be used for from ten to twenty minutes. This may be repeated every second day. The same method of procedure has been very successful in palmar contractions, etc.

Rodent Ulcer.—Treatment of this condition by the ionic method has been very successful. The ulcer is first lightly scraped over with a sharp spoon, which is not painful. About a dozen thicknesses of lint are cut out, slightly

larger than, but the same shape as, the ulcer, and saturated with a 1 per cent solution of zinc chloride. These are placed over the ulcer, with a zinc electrode on top connected to the positive pole—the negative being suitably arranged. A current of from 5 to 10 milliamperes is allowed to pass for about fifteen minutes. In many cases a single application is sufficient to cause the complete disappearance of the ulcer.

Raynaud's Disease and Chilblains.—The electrical treatment of these two conditions is often very successful, especially in the case of chilblains. This is a very annoying and obstinate condition, and the electric bath is very often the only remedy which has the least influence on it. The induction coil answers very well in the milder cases. The two electrodes are placed at opposite ends of a foot-bath, and a fairly strong current is turned on. The patient puts his feet or hands in the middle of the bath, and then gradually separates them, until the current is as strong as can be borne comfortably.

The more severe cases of chilblains, as also those of Raynaud's disease, will be found to do best with the constant current applied exactly in the same way. Any cracks in the skin must be covered over with rubber adhesive plaster before the parts are immersed. (See also CHILBLAINS, and RAYNAUD'S DISEASE.)

Disorders of Digestion.—In the treatment of some of these conditions, electricity is gradually coming to take a more important place. It is in those which are accompanied by an atonic state of the muscular coats that it finds its greatest field of usefulness. Atonic dyspepsia and constipation are examples.

Large currents and large electrodes are to be used. One large electrode is placed under the lumbar region as the patient reclines, and connected to the positive terminal. The kathode or active electrode is a disc about 4 inches in diameter, and is applied with firm pressure over the front abdominal wall, being worked to and fro over the stomach area in the case of dyspepsia, or slowly along the colon from the cæcum to the sigmoid flexure, where it is allowed to rest for from two to five minutes, for obstinate constipation. This should be done every other day for three or four weeks. The duration of each application may be from twenty to thirty minutes, and the current strength from 30 to 60 milliamperes. As the case improves, the coil may be substituted, especially if the latter is arranged to give slow interruptions. The usual result of such treatment is for the bowels to become more regular of their own accord, and to remain so afterwards.

Incontinence of Urine.—In those cases which are due to want of tone in the sphincter, where urine is expelled involuntarily during any muscular effort, a good deal can be done by the judicious application of a mild current from the induction coil. A bare metal sound is passed as far as, but not into, the bladder, which forms one electrode, while the other is an ordinary covered plate placed over the abdomen.

True nocturnal incontinence is due to the persistence of the infantile mechanism of micturition, and to be of any use the current must be strong enough to produce painful impressions. The method of application is essentially the same as given above.

Electricity is of no use in those cases of irritability of the bladder, occurring most often in females, where the urine is expelled at frequent intervals, accompanied by pain and spasm. (See also ENURESIS.)

* * * *

There are many other conditions in which electricity, in one or other of its forms, is of great value as a therapeutic agent. For these a special work should be consulted, and fortunately there are several excellent ones from which to select.

Reginald Morton.

ELEPHANTIASIS.—(See FILARIASIS.)

EMBOLISM, CEREBRAL.—(See APOPLEXY.)

EMPHYSEMA.—The treatment of chronic emphysema is of necessity confined to the alleviation of symptoms and complications, and to hindering the progress of the disease.

General and Preventive Treatment.—Chronic bronchitis, with recurrent acute attacks, is most frequently responsible for the increase of emphysema (see BRONCHITIS, CHRONIC).

Occupations which predispose to bronchitis are obviously unsuited to emphysematous patients; in addition, any laborious pursuit is disadvantageous in that it throws an extra strain both on the lungs and heart. Stair-climbing and exercises of the like character are best avoided.

Climatic treatment is often of the greatest assistance, but cannot always be afforded. The means of the patient and the cause of the emphysema must be carefully considered before a change of residence is advised. For instance, it is well known that the personal experience of an asthmatic patient is the only trustworthy guide to a suitable climate.

Speaking generally, the climates best suited to emphysematous patients have a high barometric pressure, are free from wind and dust, are warm and somewhat moist. The country should not be too hilly, and the position of the house should be carefully chosen. In this country many places on the south-west coast are quite suitable; for instance, Bournemouth, Torquay, Falmouth, Penzance, St. Ives, Lyme Regis, etc. Abroad, Egypt suits many, especially Assouan, which is relatively free from dust, and the desert itself for those who can afford to camp out. Luxor is often intolerably dusty, and the powdered Nile mud unpleasant both to lungs and nose. Cairo is not a health resort, and is unsuitable. Algiers, both at Mustapha and on the desert edge at Biskra, is fit for cases that are not very far advanced.

The French Riviera has a very treacherous climate; the cold wind from the hills and the hot sun make it dangerous. The Italian Riviera—Nervi, Rapallo, Santa Margarita—has a much more agreeable climate, and some good hotels may be found there. In Sicily, Taormina and Palermo are both good watering-places. If a moister climate seems desirable, Madeira, Teneriffe, or Las Palmas may be recommended.

It must not be forgotten that some emphysematous patients who owe their trouble to spasmodic asthma are more comfortable in London than elsewhere, in spite of, or perhaps because of, the fogs.

Drug Treatment.—It is doubtful if any drug treatment can have an influence on the degenerative changes which take place in the lung tissue, yet long experience makes it certain that patients feel more comfortable while taking certain medicines. If there is any tendency to gout, arterial degeneration, or asthma, potassium iodide in intermittent courses of two or three weeks is often of value:—

R Potassii Iodidi		Potassii Bicarbonatis	gr xv
Ammonii Carbonatis	āā gr iij	Aquæ Camphoræ	q.s. ad ʒj

Thrice daily after meals.

To this mixture liquor potassii arsenitis 3 min. may be added, or if there is any tendency to spasm of the bronchial tubes, 6 to 12 min. of the tincture of belladonna. If there is anæmia, and in some cases where there is renal degeneration, the addition of iron is useful:—

R Potassii Iodidi	gr iij	Potassii Bicarbonatis	gr xv
Ferri et Ammonii Citratis	gr xv	Aquæ Pimentæ	q.s. ad ʒj

Thrice daily after meals.

Some emphysematous patients are stout; in these cases, if the kidneys are sound, treatment of the obesity by diet and regulated exercises with massage is of great value. The article on OBESITY should be consulted. Other emphysematous patients are thin; here the dietetic treatment should be like that for tuberculosis. The food should be plentiful and contain much fat; the administration of cod-liver oil, with or without malt extract, is generally helpful. If the oil is distasteful, one of the many proprietary preparations or substitutes may be used in its place.

Compressed Air.—Emphysematous patients are at times undoubtedly benefited by a course of compressed-air baths. Unfortunately, there are very few places where they are available in this country. At the Brompton Hospital a small iron room has been so arranged that the air pressure within can be gradually raised while the supply of fresh air is abundant; the patient is placed in the chamber and the pressure is gradually raised, until after twenty minutes it equals $\frac{3}{4}$ to 1 atmosphere; the air remains at this pressure for one hour, and is then slowly decompressed. While the patient is in the bath he feels relieved, and after a course of twenty or thirty baths, the relief is found to be persistent. The treatment is unsuitable if there be obesity, chronic kidney disease, arterial plethora, a tendency to hæmoptysis, etc.; and in some patients subject to asthma, exposure to the pressure seems to determine an attack. Apparatus for the inhalation of air under pressure and exhalation into rarefied air are useless.

Complications.—Bronchitis and cardiac failure with pulmonary congestion and œdema are the most common complications of emphysema. The treatment of these conditions is discussed in the articles on BRONCHITIS, and CONGESTION, PULMONARY.

Cecil Wall.

EMPYEMA.—When by the aid of the exploring syringe the presence of an empyema has been definitely proved, the treatment resolves itself into that indicated in the case of any other collection of pus, namely, the provision of free, unhindered drainage.

Satisfactory drainage of the pleura can be secured only by means of an opening large enough to admit a full-sized drainage tube, and for this purpose removal of a portion of one or more ribs is necessary. It may, however, be wiser in certain circumstances, either to aspirate an empyema, or to make a simple incision into it.

1. *Aspiration.*—Although an empyema has undoubtedly been cured on a few rare occasions by one or more aspirations, the chance of cure in any given case is so remote, and the importance of freeing the lung as soon as possible from compression by the fluid is so great, that it is unwise to aspirate except as a preliminary to some form of drainage.

If the empyema is a large one and the patient is much distressed, and especially if the heart is displaced, aspiration should be performed forty-eight hours before the chest is opened. The general condition of the patient is by this means greatly improved, so that an anæsthetic may safely be given and the chest opened without anxiety. Again, when the heart is displaced, experience has shown that sudden evacuation of a large quantity of pus, resulting from a free opening into the chest, is exceedingly dangerous, numerous instances of fatal syncope having occurred under these circumstances. This danger will be avoided by aspiration, the slow withdrawal of part of the pus allowing the heart to gradually return to its normal position without risk. If it be decided to attempt aspiration for either of the above reasons, the needle used must have a large bore, in order to guard, as far as possible, against the liability to blocking.

2. *Incision* is suitable in certain cases, namely (a) Those in which the patient

is so ill that it is important to do what is necessary as quickly as possible, and without disturbing the patient more than is absolutely necessary; (b) Where aspiration is indicated but has failed owing to the thickness of the pus; (c) Those in which a general anæsthetic cannot be given or is not available; and (d) Where the character of the assistance available, and the circumstances of the case, necessitate the adoption by the practitioner of the simplest and quickest method of treatment that is likely to be successful.

The patient should lie on the back or to a slight extent rolled on to the sound side, with the side to be operated upon projecting well over the edge of the bed or table. The skin of the chest wall having been painted with 2 per cent solution of iodine in alcohol, and all necessary precautions having been taken to preserve strict asepsis, the site of the incision must be decided upon. If the empyema involves the whole chest, the incision should be made in the seventh intercostal space immediately in front of the posterior axillary fold, i.e., at the anterior border of the latissimus dorsi. If the empyema is a small localized one, the presence of pus at the dullest part must be verified with an exploring syringe, and the incision made at this spot. The upper edge of the rib bounding the space below is now fixed with the finger nail, and the point of the knife having been placed upon the skin immediately above the finger nail, it is quickly pushed into the chest and rapidly carried along the upper border of the rib for about two inches. A pair of sinus forceps is now passed along the knife into the chest, the knife withdrawn, the forceps widely opened, the pus allowed to escape, and a drainage tube passed through the incision.

The great disadvantage of this operation is that, owing to the closeness of the ribs to one another, the tube is liable to be compressed, and the drainage thereby rendered unsatisfactory. In order to combat this tendency as far as possible, a thick-walled drainage tube should be used, of as large a calibre as the intercostal space will admit, and further, two tubes may be inserted side by side.

Dressings are now applied, and the patient is returned to bed. For details of after-treatment see below.

3. *Resection of a Rib.*—This is the operation of choice, and should be adopted in all cases save those mentioned above. The operation is more difficult than incision and takes longer to perform, and is therefore a greater tax upon the patient's strength. In addition, a general anæsthetic is usually necessary. On the other hand, it has many great advantages over incision; the chief being that (a) The size of the opening ensures free and continuous drainage; (b) The large masses of breaking-down lymph so often present can be scooped out, and the time of healing thereby curtailed; (c) A finger can be introduced into the cavity, and its size and shape and the condition of the lung ascertained. In many cases, moreover, adhesions between lung and pleura may be gently separated, and a more rapid expansion of the lung thus secured.

The anæsthetic, preferably chloroform, having been administered, the patient is placed in the position already described, the skin is cleansed, and all other preparations are made. In a general empyema a portion of the seventh or eighth rib immediately in front of the edge of the latissimus dorsi should be removed, and in a localized one a portion of rib over the dullest part should be chosen. The incision, about three inches in length, is made midway between the borders of the rib, dividing everything down to the bone, including the periosteum. With a rugine the periosteum is now carefully separated, first from the outer and then from the inner surface of the portion of rib exposed, great care being taken not to open the pleura prematurely, and to avoid tearing the periosteum lining the subcostal groove and so possibly wounding the intercostal vessels and causing troublesome hæmorrhage. About one and a half inches of

the rib, thus stripped of periosteum, are now removed by rib shears or bone-cutting forceps.

The intercostal vessels remain imbedded in the periosteum that lined the subcostal groove, and must be carefully avoided in opening the pleura. This is best done by pushing a director into the chest through that part of the exposed periosteum that corresponds to the upper border of the rib, a pair of dressing forceps being then passed along the groove of the director and withdrawn widely opened. Through the opening thus made the cavity may be explored, its size and the condition of the lung ascertained, and any large masses of lymph hooked out with the finger, or with the finger and a lithotomy scoop combined. If the quantity of pus is large, and especially should displacement of the heart be present, it is important not to allow the cavity to empty very quickly, in order to prevent, as far as possible, the danger of sudden syncope.

Hæmorrhage is, as a rule, slight, and quickly ceases; should, however, troublesome bleeding take place from a vessel deep in the wound where ligature is impossible, a pair of Spencer Wells' forceps may be applied and left in position for twenty-four hours. If an intercostal vessel be found to be bleeding, sufficient rib should be rapidly removed to enable the vessel to be under-run and ligatured on either side of the bleeding point.

The cavity being emptied and all masses of lymph removed as far as possible, adhesions between the lung and parietes, if recent, may with advantage be broken down by the finger, as this will greatly aid expansion of the lung, and thus materially lessen the time required for healing. The drainage tube must now be inserted. This should be a short tube of very wide calibre, and should be pushed in only far enough to ensure its inner extremity being flush with the surface of the parietal pleura. The tube may be fixed for the first few days by means of two silkworm-gut sutures passing one on either side through the wall of the tube and the superficial tissues. Later, when the sutures cut out, the tube may be replaced by a flanged one held in position by tapes passing round the chest. Abundant *antiseptic* dressings must now be applied and the patient returned to bed.

Should an empyema be present on both sides, the larger collection should be drained, and the opposite side aspirated as a preliminary to opening and draining a few days later.

TREATMENT AFTER OPERATION.—Dressings for the first few days, while the discharge is large in amount, should be changed frequently; later, daily dressing will be sufficient. At the dressings the greatest care must be taken, by strict attention to all the details of surgical cleanliness, to prevent infection of the wound, for only by so doing can rapid convalescence be established and complications avoided.

Every means must be adopted to increase the patient's strength, and as soon as possible he must be got out of bed, then out of doors, and later if possible to the seaside.

In order to help the lung to expand, deep breathing exercises must be encouraged, and in children the use of blowing toys will be found helpful.

The tube must be kept in position as long as any discharge continues; the length of time depending largely upon the duration of the empyema before draining, this determining the degree and density of the adhesions which bind down the lung and prevent its expansion.

If the empyema has been drained without any undue delay after its formation, the lung will usually expand steadily, and the case terminate satisfactorily under the treatment above described; but in neglected cases in which the lung has long remained compressed by a large collection of pus, it may remain permanently airless and fibrotic after the empyema has been drained.

If after some weeks of drainage without apparent improvement this state of affairs is suspected, the size of the cavity should be carefully estimated at regular intervals by means of a probe passed in various directions. In this way it can be definitely decided whether the lung is slowly expanding or whether the case is at a standstill. In the former case every effort should be made to increase the rate of expansion of the lung by the use of deep breathing exercises and by encouraging the patient to move about freely in the fresh air, so as to increase the amplitude of the chest movements. If, however, the lung shows no sign of expansion, some further operation, such as Estlander's operation and its modifications, will become necessary in order to allow the chest wall to fall in and the cavity thus to become obliterated.

F. J. Steward.

ENCEPHALITIS, ACUTE.—(See **POLIOMYELITIS.**)

ENDOCARDITIS.—(See **RHEUMATISM, ACUTE.**)

ENDOMETRITIS, CHRONIC.—This term is applied to conditions where the glandular or interstitial tissue of the corporeal endometrium is thickened as the result of septic or gonococcal infection. It is often applied to cases where the endometrium is thickened as the result of a diffuse adenomatous growth. The endometrial condition, whether the result of germ infection or adenomatous growth, may be associated with a general thickening of the substance of the uterus. The cervical mucosa may or may not be affected. Hæmorrhage and discharge are the two chief symptoms. The hæmorrhage is generally of the menorrhagic type. The discharge may be clear mucus or mucus streaked with pus.

Iron, ergot, hot vaginal douches, and time may cure some of the cases which are due to septic or gonorrhœal infection. When menorrhagia is pronounced, and does not yield to this treatment, curetting may be tried. If a discharge is the chief symptom, curettage does not offer so good a prospect of relief. In cases where thickening of the uterine substance is highly marked, the curette often fails to give relief.

The operation of curettage is carried out as follows : The instruments required are a duckbill speculum, two pairs of volsella forceps, a uterine sound, a set of Hegar's dilators, a sharp curette, a pair of uterine dressing forceps, and some swabs of sterilized cotton-wool. All the instruments must be carefully boiled, and then placed in a tray or basin of carbolic lotion.

The patient is anæsthetized, placed in the lithotomy position, and kept there by means of a Clover's crutch. The external parts are then well washed with soap and water and swabbed over with a solution of corrosive sublimate 1-1000. A douche of the same antiseptic is given, to thoroughly disinfect the vagina. A careful bimanual examination should then be made, to determine accurately the condition of the pelvic organs. The cervix is exposed by means of the duckbill speculum, and the anterior lip seized with a volsella, so as to draw it down and at the same time to fix it. The uterine sound is then passed to determine the direction and length of the uterine cavity. The traction with the volsella will have caused an apparent lengthening of about half an inch. A No. 4 or 5 Hegar's dilator is then introduced into the uterine cavity. Firm steady pressure will overcome the resistance of the os internum. The rapidity with which dilatation can be carried out will depend on the rigidity or otherwise of the os internum. If much resistance is met with at this point, dilatation must be carried out slowly, each dilator being left in position for a minute or longer. Often by the time No. 12 is reached much of the resistance originally met with has passed away, and the remaining dilators can be passed without difficulty. Unless it is desirable to introduce the finger into the uterus, dilatation

may stop after No. 14 has been passed. The curette is now used—a sharp looped one is the best. It should be employed firmly and thoroughly, so as to scrape the whole of both the anterior and posterior surfaces of the uterus. Sometimes the other hand may be placed with advantage on the abdomen, to steady the fundus of the uterus during the procedure. Thick flakes of mucous membrane generally come away with the curette. There need be no fear that the curette will perforate the uterus. In some rare cases, where the tissues above the os internum are very thin, or where the fundal tissues are very soft, the uterus may be perforated; but this always takes place during the process of dilatation, and not during the curetting. If such an accident should occur, the dilatation must be stopped. When proper antiseptic precautions have been taken, and the interior of the uterus is not actively septic, no untoward symptoms will result.

After the curettage is completed the vagina should be swabbed out with an antiseptic solution, but it is not necessary to pack it with gauze. As a rule there is little or no discomfort after this operation if the vagina be not plugged. A douche may be given about the third or fourth day after the operation, and repeated once or twice.

ENURESIS (in Childhood).—Enuresis as a neurosis seems to be the result of hypersensitiveness of the lumbar centres of micturition, and of deficient inhibitory control on the part of the higher cerebral cortex over the lower centres in the spinal cord. It is one of the indications of general nervous instability. It may be hereditary, congenital, or acquired. Sometimes it is a familial affection. When nocturnal only, enuresis may be due to unsuspected epilepsy.

Cases in which nervous instability is the sole cause are the most intractable; but in the great majority some exciting cause is present as well.

In a few, want of proper training may keep up the habits of infancy. Every child has to be taught to control its bladder and make known its desire to empty it. It usually learns to do so before the age of two. If incontinence is habitual after the age of three, it is a morbid manifestation. It is most serious when it is constant, day and night, and is usually then associated with some form of mental enfeeblement, or with spina bifida occulta, in which case it is incurable. Sometimes it is due to pressure on the cord by tuberculous or other lesion of the vertebræ.

The chief exciting causes of enuresis when not of purely nervous origin are: (1) Adenoid vegetations; (2) Local conditions, both within and without the bladder, which render it and the spinal centres irritable; (3) Constitutional defects, such as diabetes mellitus and insipidus, anæmia, and general debility; and, far more rarely, (4) Chronic interstitial nephritis.

Adenoid Vegetations.—These are a most potent cause of nocturnal enuresis, but probably they never give rise to diurnal incontinence. Enuresis may be part of, or the result of, night terrors, which are also common in the subjects of adenoid vegetations. But night terrors in these cases are probably set up by partial asphyxia, which stimulates the respiratory centres and perhaps also

the vasomotor centres in the medulla. Thus an increased flow of urine may occur into the bladder, which empties itself because the cerebral centres of control are inhibited by fright.

Causes of Irritation within the Bladder.—Stone, cystitis from tuberculous disease, and new growth need only be mentioned here as possible causes. Vesical irritability may be caused also by hyperacidity of the urine, and by bacteriuria, and sometimes by polyuria.

Hyperacidity of Urine.—Doubts have been cast recently on the reality of this cause of enuresis, but certainly enuresis is associated at times with highly acid urine, depositing urates in large amount, uric acid, or oxalates. The enuresis in such cases is diurnal and nocturnal too. It is usually readily cured for the time being by a few doses of citrate of potash, especially if tinct. hyoseyami be added. Many believe that excessive meat diet is the cause, and certainly, in some cases, restriction in nitrogenous diet is efficacious.

Bacilluria, Coliuria, *B. coli* Infection.—Infection of the urinary tract by *B. coli* is not an uncommon cause of enuresis, incontinence, and frequent and precipitant micturition.

The urine is highly acid, sp. gr. 1010-20, clear at first, but on standing becomes neutral or alkaline and turbid, the turbidity being unaffected by heat or reagents. It has a characteristic offensive odour, and stains napkins or underclothing yellowish brown. A few pus cells and a trace of albumin may be found. On centrifugalizing and staining with methylene blue, *B. coli* are easily seen with an oil-immersion lens. *B. coli* flourish in an acid medium, and the treatment of coliuria consists chiefly in rendering the urine alkaline. The citrate and acetate of potash, 5 gr. of each, may be given every four hours, and the amount of alkalies increased by 20 gr. daily until 160 to 180 gr. are taken in twenty-four hours. Large doses of the citrate of potash alone sometimes set up profuse diarrhoea. The alkaline treatment should be continued for several weeks, as cessation is often followed by renewal of the symptoms. Opinions are divided as to the efficacy of hexamethylenamine. The *B. coli* is said to thrive in urotropinized urine, but the writer has frequently noticed improvement when hexamine in doses of 5 to 10 gr. has been added to the alkaline mixture. Theoretically this treatment is unsound, for hexamine is only converted into formaldehyde in an acid medium. Hence its combination with acid phosphate of sodium has been advocated. Benzoate of sodium and ammonium in doses of 5 to 10 gr. are sometimes useful. Hyoseyamus in 10- to 15-min. doses of the tincture allays vesical irritability. To prevent re-infection it is desirable to attack the *B. coli* at their source in the bowel. Constipation should be treated, and the rectum washed out with boracic or saline solution. The usefulness of salol and other so-called intestinal disinfectants is problematical.

Vaccine Therapy is unnecessary in uncomplicated coliuria, but when pyuria, with pyrexia and evidence of pyelocystitis, is present, a vaccine should be prepared from a pure culture of the organism isolated from the patient's own urine. Three millions is a suitable dose for a child one year old, and 25 millions for an adult. The dose should be repeated in two days' time, and the interval then gradually extended in accordance with the patient's progress. For a child aged five years suffering from enuresis due to bacilluria :—

R Tincturæ Hyoseyami	℥x	Hexamethylenaminæ	gr. v
Potassii Citratis		Spiritus Chloroformi	℥iij
Potassii Acetatis	āā gr. xv	Infusi Buchu	ad 3ss
3ij-3iv every four hours.			

Alkalinity of the Urine without cystitis is also associated with enuresis. The urine may be alkaline from triple phosphates, sometimes it is neutral. It may be of low specific gravity—1002-1005; it may contain a trace of albumin, and

it is always marked by increase in quantity ; in fact, polyuria is the condition present. A characteristic is, that the child, on being waked at night to pass water, does so in considerable quantities, but after a short interval is found to have passed as much again in bed.

In some instances the complaint may be traced to excess of farinaceous and saccharine food, for it may be cured by supplying a rigid antidiabetic diet for a few days (Percy Lewis).

It must be borne in mind, however, that enuresis and polyuria, with a precisely similar condition of urine, are strongly suggestive of *chronic interstitial nephritis* in children. Polyuria in itself is sufficient to cause enuresis.

Causes of Irritation outside the Bladder.—Of these may be mentioned phimosis, balanitis, and vulvitis ; but in some cases the incontinence may be the cause, not the consequence, of the irritation.

Oxyurides and constipation sometimes give rise to enuresis.

Irritability of the bladder may still produce incontinence, night and day, when the original cause of irritation has been treated or removed. The presence of very small quantities of normal urine in the bladder is sufficient to excite it to contract. At short intervals there is a sudden call to micturate, which must be obeyed at once (pollakiuria).

Atony of the Sphincter is not a common condition, but occasionally gives rise to incontinence. The urine drips or trickles away without frequent and distressing desire to pass it. Such cases, in both sexes, may sometimes be cured by the passage of a sound.

Electricity, in the form of faradism, one pole being placed in the urethra or on the perineum, and the other to the back or suprapubic region, is sometimes of service when the sphincter is weak.

Direct massage of the neck of the bladder by a finger introduced into the rectum has been recommended ; but the method is obviously objectionable, and should not be employed except as a last resource.

The treatment of an irritable bladder which will contain only small quantities of urine consists in training it to hold more. The child should be kept in bed, and instructed to micturate at gradually increased intervals. The diet should be bland, without excess of starchy, farinaceous, saccharine, or nitrogenous articles. Water or barley-water may be given freely. It is a mistake, in any case of enuresis, to restrict fluids, except shortly before bed-time. Tea and coffee should of course be prohibited.

Tincture of hyoscyamus, in doses of 1 to 30 min. or more, is a valuable vesical sedative. It may be given with citrate of potash and infusion of buchu.

In inveterate cases of irritable contracted bladder, gradual expansion of the organ by injections of weak boracic lotion, combined with local application of electricity, is said to be successful.

Treatment by Epidural Injection has been advocated in France and America. It consists in injecting normal sterilized saline solution in quantities of one and a half to five and a half or more drachms into the sacral epidural space. It is supposed to act by irritating the cauda equina, and thus conveying impulses to the lumbar centres, which are thought to be incited thereby to exert tonic or inhibitory influences over the bladder. The injections are made with an ordinary syringe, having a needle of a length of $1\frac{1}{2}$ inches. The patient stands, or lies on his side with thighs flexed. The site of injection is the membrane closing the lower end of the sacral canal, which is indicated by a triangular depression situated at the posterior termination of the intragluteal fossa, and between the posterior and inferior processes of the last sacral vertebra. The needle is inserted at this point and thrust forwards and upwards into the sacral canal. No anæsthetic is used. The operation is said to be free from danger

if ordinary precautions to ensure surgical cleanliness are adopted. Success is claimed in a sufficiently large number of cases to warrant employment of the method when other means have failed. It is admitted that it is by no means uniformly curative. Its effects, if any, are probably psychical. *Hypnotic suggestion*, in a very few carefully selected cases of enuresis of purely nervous origin, may be recommended.

General Treatment.—Whatever may be the cause, the inconvenience occasioned by nocturnal enuresis may be lessened by waking the child at set intervals, to pass water. Accidents commonly happen when the child lies on his back. Therefore he should be taught to sleep on one side. A "bobbin" or some hard object strapped to the small of the back will wake him should he turn over.

Restriction in fluids just before bed-time, and in stimulant diuretics such as tea, coffee, mustard, pepper, spices, meat juices, sugar, and starch (in some cases), should be enjoined.

Any of the mental and physical conditions which excite night terrors may cause enuresis, and therefore require similar treatment. Punishment of any kind is rightly condemned in any case of enuresis occurring in a child upwards of three years. But few can have escaped a slapping in infancy for this particular crime, and the nurse's palm has taught many of us to control our bladders by night. Medical men only see cases in which such primitive treatment has failed.

Constipation should be relieved. Evacuation of the bowels in the evening, before bedtime, will sometimes cure nocturnal enuresis.

Treatment by Drugs.—The utility of some has already been mentioned. It would be impossible to enumerate all the drugs which have been found invaluable by some, and useless by other, practitioners. Consideration of the various causes of the complaint will suggest appropriate remedies.

Atropine and belladonna should not be given by routine in every case. Children who wet the bed occasionally should not be poisoned indiscriminately with belladonna for months together. The physiological action of belladonna in full doses is to cause temporary paralysis of the bladder and to lessen secretion of urine. In some cases such results are beneficial, in others not. Belladonna is useless when sphincter control is weak, also in cases in which the tendency to enuresis is kept up by local and constitutional conditions. It is seldom useful in cases of both diurnal and nocturnal enuresis.

It is most valuable in cases of habitual nocturnal enuresis. The drug should then be pushed to full doses (10 to 40 min.* of the tincture for a child of 10 to 12) and be given at night only, with 10 gr. of one of the bromides. Or atropine may be given in 1-min. doses of the liq. atropinæ sulph., 4 gr. to 1 oz., gradually increased until the physiological effect is produced. If no good effects follow a few weeks of belladonna treatment, the utility of its continuance is doubtful. The disadvantage of keeping a child for months in a state of chronic belladonna intoxication is obvious. Few parents can be induced to persevere with the treatment after one or two experiences of children rendered half blind, staggering, delirious, and unable to swallow, in consequence. The ill effects can, however, be reduced by giving belladonna or atropine at night only.

The writer has found better results from giving hyoseyamus, citrate of potash, and buchu, than from the belladonna treatment alone, but in some such cases it is probable that he was treating coliuria unawares.

Cantharides has been recommended when there is weakness of the sphincter. Lycopodium, in doses up to a drachm of the tincture, may be useful as a bladder sedative. Ergot in atony of the bladder; antipyrin as a general nerve sedative; valerianate of zinc in $\frac{1}{3}$ - to $\frac{1}{2}$ -gr. doses; rhus aromatica in dose

* Doses of this size should be employed with caution.—AMERICAN EDITOR.

of 10 to 15 min. of the fluid extract, as a stimulant, diuretic, and tonic, may all be useful when the conditions which indicate their use are present. Arsenic, strychnine, and nux vomica and iron may be required. In a few instances, where there is mental and physical evidence of thyroid insufficiency, thyroid extract may be beneficial.

Nervous Retention of Urine is not uncommon in boys. The writer has known it to occur in father and son. The father, throughout his life, could never use a public urinal, nor pass water if anyone was by. The son suffered much at school from the thoughtless teasing and practical jokes to which he was subjected by his schoolfellows on account of a similar failing. Fortunately, no further ill consequences ensued; but in such cases, as the affection cannot be overcome by drugs or strength of will, common-sense instruction should be given, in order to enable the patient to conceal it.

Hysterical retention of urine in young girls never needs active treatment by passage of a catheter. (See also ELECTROTHERAPEUTICS.) *Leonard G. Guthrie.*

EPIDIDYMITIS, ACUTE.—(See GONORRHEA.)

EPIDIDYMITIS, TUBERCULOUS.—Tuberculous disease affects the epididymis in two forms—an acute and a chronic.

Acute tuberculous epididymitis is not infrequently a preliminary stage of the chronic form. The symptoms are slightly less severe, the pain is less intense, than in acute gonorrhœal epididymitis. (See GONORRHEA.) A urethral discharge sometimes accompanies the epididymitis and increases the resemblance to the gonorrhœal affection. The discharge is, however, less creamy and copious, the tubercle bacillus may be present, and the gonococcus is absent. There is a tendency to abscess formation in the tuberculous epididymis, and there may be tuberculous lesions in the prostate, vesicles, and second epididymis, or in the urinary organs. There is frequently a strong tuberculous inheritance, and in many cases the discharge cannot be referred to any recent or remote connection.

In acute tuberculous the treatment should be directed to relieving the symptoms. The patient is confined to bed, and the swollen testicle supported upon a cushion. Equal parts of extract of belladonna and glycerin are smeared over the scrotum, and hot fomentations applied; or the whole scrotum is enveloped in a thick layer of antiphlogistine and covered with cotton wool, the application being renewed daily. A brisk saline purge is administered. Urethral injections should be avoided. The acute inflammation usually subsides in a week or ten days, and gradually passes into the chronic form of tuberculous inflammation, or an abscess may form and rupture on the surface; in the latter case the abscess is opened and the cavity lightly packed with iodoform gauze.

In the chronic form there are several types of cases: (1) A solitary tuberculous focus in one epididymis; (2) Tuberculous disease of the epididymis with foci in other parts of the genital system (seminal vesicles, prostate); (3) Disease of the epididymis with tuberculous infection of the urinary system (bladder, kidneys); (4) Disease of the epididymis with or without urinary tubercle, and with active tuberculous foci in other parts of the body (joints, spine, lungs).

The treatment of chronic tuberculous epididymitis is of two kinds: non-operative or operative.

Non-operative treatment includes climatic, general, and local treatment. A genial, sunny climate with an even temperature, nourishing food, with plenty of rich milk, should be prescribed. Cod-liver oil, creosote, iodide of iron, are useful tonics. Care should be exercised in protecting the diseased testicle from injuries, even of the most trivial kind. The scrotum is packed in a layer of

cotton-wool, and slung in a well-fitting suspensory bandage. Sexual intercourse is absolutely interdicted. If the nodule softens and breaks down, the skin of the scrotum should be cleansed and the abscess opened. A sharp spoon may be used and the cavity packed with a pledget of iodoform gauze, but no attempt need be made to eradicate the whole disease by this means. The cavity heals readily, but there is a tendency to recurrence of the "abscess," and this is treated in the same way.

The use of tuberculin (Tuberculin R.—Allen and Hanburys) is an important part of the non-operative treatment. Improvement under tuberculin may be rapid or may be delayed for some months, but unpromising cases may clear up in a remarkable manner. The treatment consists in the hypodermic injection of very small doses. Injections commence with $\frac{1}{2000}$ mgm, and should no reaction follow, another injection of similar strength is given at the end of a week. These are repeated each week for several weeks before increasing the dose. Should the patient complain of malaise, pain in the back, or increased local tenderness after the injection, an interval of a fortnight should be allowed to elapse before the next one. The dose is gradually raised to $\frac{1}{1500}$, $\frac{1}{1000}$, $\frac{1}{800}$, $\frac{1}{600}$, $\frac{1}{500}$, and sometimes even higher doses may be used. The duration of the treatment must vary with the progress of the case. The progress is usually slow, and the patient should be warned that the treatment may continue for eighteen months or two years.

The choice of radical operative measures lies between castration and epididymectomy, and the latter operation is to be preferred wherever possible. If the disease has penetrated the testicle and spread extensively in its substance, castration is indicated; but this may only become evident during the operation, and before operative measures are undertaken permission should always be obtained for removal of the testicle should this be considered necessary.

When the disease affects one epididymis, without foci elsewhere, epididymectomy should be performed, and this should be followed by a course of general and tuberculin treatment. Where foci are present in other parts of the genital system the same line of treatment should be adopted, both epididymes being removed if tuberculous. Orchidectomy should be reserved for those cases where the testicle is involved. The retention of the testicles, even when the patient is aware of the abolition of their sexual function, has an important mental effect. Operations involving removal of the seminal vesicles and prostate are sometimes performed, but are not satisfactory in the majority of cases. Where these organs are affected, removal of a tuberculous epididymis or testicle, followed by general and tuberculin treatment, gives better results.

When the urinary system is involved in the tuberculous infection, radical operation upon the genital tubercle is contra-indicated, and the same attitude must be adopted as towards a case where tuberculous disease is present in other parts of the body. While this may be taken as the rule, there are exceptional cases where a more radical method of treatment may be considered advisable. The writer has performed nephro-ureterectomy and orchidectomy upon a patient for tuberculosis confined to one kidney, ureter, and epididymis, with most fortunate results.

J. W. Thomson Walker.

EPILEPSY.—An epileptic attack is a *symptom*, which may depend on a variety of different causes, the detection of which affords the necessary indications for the treatment of the case.

Epilepsy proper is a *disease* characterized by a tendency to the recurrence of epileptic attacks. The fits may be severe (*grand mal*) or slight (*petit mal*). Most epileptics have both major and minor attacks; when the former are met with alone, the outlook is distinctly more favourable than when both forms

occur; cases in which there are only minor attacks are usually the most intractable.

It is customary to subdivide cases of epilepsy into two groups—*idiopathic* and *organic*. The first includes those cases in which no obvious cerebral lesion exists, while to the second belong those in which gross intracranial disease is present.

Epileptiform or Jacksonian attacks are synonymous terms applied to localized convulsive fits, which begin in a certain muscular group, have a deliberate spread, are usually unattended with impairment of consciousness, and are followed by a degree of temporary paralysis in the parts convulsed. It is important to remember that the occurrence of Jacksonian fits does not necessarily imply the existence of gross cerebral disease.

Reflex epilepsy is a term sometimes used to denote those uncommon cases in which the disease is apparently dependent on an extracerebral cause.

TREATMENT may be considered under the following headings: (1) The means by which it is possible, in some cases, to arrest an attack; (2) The treatment of an epileptic attack; (3) Status epilepticus; (4) General measures and method in the treatment of the disease; (5) Drug treatment; (6) Surgical treatment, with special reference to organic epilepsy; (7) The colony system.

1. Arrest of an Attack.—When there is a distinct aura, it is, in very exceptional cases, possible to avert an impending attack. Thus, a powerful mental or muscular effort is, in rare instances, effective. The inhalation of amyl nitrite, immediately the warning is felt, is sometimes successful; and where this is found to be so, the patient should carry with him a box of capsules. Strong smelling-salts occasionally act in a similar way.

When the aura is localized to one hand, the fit may sometimes be arrested by firmly grasping the wrist of the affected side. If it is found that a fit can be thus averted, the patient may wear a strap or tape fastened conveniently round the wrist, which he can immediately tighten on the first sensation of the aura. This procedure may result only in a postponement of the attack, which, when it does occur, may be of unusual severity.

2. Treatment of an Attack.—The physician, if present at the onset, should, firstly, place the patient in the recumbent posture; secondly, loosen the clothes about the neck and chest; and, thirdly, insert between the teeth a tongue depressor, cork, or some such object, in order to prevent tongue-biting. Little advantage is to be gained by attempting to cut short the attack; but should the tonic phase be unduly prolonged, or should a second attack follow immediately upon the first, a few whiffs of chloroform, or an inhalation of nitrite of amyl, may be administered.

The patient's friends may be told that there is practically no danger, for an epileptic fit is in itself an extremely uncommon cause of death.

Vomiting occasionally occurs towards the end of a fit. If any tendency to this is observed, the patient should be turned on his side, in order that the risk of regurgitation of the vomited matter into the respiratory passages may be avoided, an accident which has been known to be attended with fatal results.

Post-epileptic Phenomena.—After the termination of the fit, the patient often falls into a deep sleep, in which it is well to leave him undisturbed. Severe headache, often frontal, is an almost constant sequel, and is usually relieved by a 10-gr. dose of phenacetin. Hysterical seizures sometimes follow. Since it is especially in association with *petit mal* that these phenomena are prone to occur, their true nature is apt to escape recognition. The immediate treatment is that of a true hysterical fit, while a therapeutic course, appropriate to the epileptic condition, must be instituted. Among other post-epileptic states to which reference may be made are the outbursts of maniacal excitement which sometimes follow a fit, which may constitute a source of danger to the

community. For such a case, if it is beyond the control of a responsible attendant, an asylum is the proper place.

When post-epileptic automatism is a feature of the case, it is hardly necessary to say that the patient's relatives and fellow-workmen should be instructed to keep a close watch upon his movements.

3. Status Epilepticus.—This grave and often fatal condition is fortunately rare. Inhalations of chloroform, or nitrite of amyl, may check the attacks, but their effect is often only temporary. Bromides are usually ineffectual. Chloral hydrate is generally the most effective drug in these cases. It should be given in a dose of 30 to 60 gr. by the rectum, the dose being repeated, if necessary, in the course of an hour. Hypodermic injections of hydrobromate of hyoscyne have been strongly recommended by Sir William Gowers, in doses of from $\frac{1}{150}$ to $\frac{1}{50}$ gr., and may be given should the last-named drug prove a failure. Morphia, administered hypodermically, in doses of $\frac{1}{4}$ to $\frac{1}{2}$ gr., has met with the approval of some authorities. Strychnine is undoubtedly most valuable, especially when the attacks have continued for some time, and when there are signs of increasing general and cardiac weakness. If the drugs already mentioned have proved unsuccessful, $\frac{1}{50}$ gr. may be given hypodermically, and repeated, if necessary, according to the effect produced.

Respiratory embarrassment, due to falling back of the tongue, may prove fatal during the status epilepticus. If there is reason to suspect this accident, the patient should be turned on his side, and the tongue drawn forward with forceps.

4. General Measures and Method in the Treatment of the Disease.—The first necessity is a correct diagnosis, a matter by no means always easy, since the account given by the patient, or his friends, often constitutes the only positive evidence bearing upon the diagnostic problem.

Having made his diagnosis, the physician's next duty is to conduct an *exhaustive enquiry into the patient's habits and general health* in relation to the occurrence of fits, hoping thereby to detect evidence as to possible immediate exciting causes. Thus dietetic irregularities, constipation, unnecessary excitement, may in different cases appear to be of causal import, requiring special attention when regulations as to treatment are laid down.

Anæmia, if present, calls for correction, as does any other intercurrent departure from the normal state of health. A careful examination as to the existence of any *peripheral source of irritation* is necessary. Thus, the presence of intestinal worms, adenoids, an adherent prepuce, aural or nasal polypus, bad teeth, or an error of refraction, may play a part in determining the occurrence of convulsions; but the tendency to regard them as of causal import is commonly exaggerated. The indiscriminate operative treatment of local conditions, such as the practice of tenotomy in cases of so-called eye-strain, is, in the light of our present knowledge, to be condemned. Unless the local abnormality is so pronounced as of itself to demand local treatment, or unless there appears to be very strong reason for relating it directly with the incidence of the attacks, it is advisable to delay any operative measures until the patient has undergone a thorough and prolonged therapeutic course, after which, if the fits still persist, the operative treatment of the local condition, with the hope of relieving the epilepsy, may be undertaken as a *dernier ressort*.

The *general treatment* of epilepsy is almost as important as the drug treatment. Precise instructions should be laid down, adapted to meet the requirements of each case. Regularity and moderation are to be the guiding principles. The benefit which ensues from these general measures has been amply demonstrated by the colony system, to which special reference will be made later.

The *diet* best suited to epileptics has been the subject of considerable discussion; but beyond the advisability of limiting the quantity of red meat,

which should be taken not more than once a day, cutting off articles known to be indigestible, with special reference to the individual case, and avoidance of over-eating, it is unnecessary to lay down further directions.

A chlorine-free diet has been lately recommended, and its efficacy confirmed by a number of observers. The principle involved is the substitution of the bromides for the common salt of everyday use. There is, as yet, however, no conclusive evidence to show that the results so obtained are superior to those seen when the bromide salts are administered in the usual way, and any little advantage so derived is counterbalanced by the inconvenience involved in the preparation of a special diet, since this practically places the method within the reach of the wealthier classes only, or of special institutions.

The patient must take his food leisurely. The time of meals should be adhered to with strict punctuality, and the last meal of the day should be so arranged as to allow of completion of digestion before the patient goes to bed.

Alcohol should be forbidden. Tobacco may be allowed in moderation. Sexual excess is to be avoided.

Attention to the bowels cannot be too strongly insisted upon, for constipation is a common exciting cause of the attacks. Where there is this tendency, a small dose of cascara may be given in combination with the bromides or other drugs which the patient is taking, the dose being altered as occasion demands.

Outdoor exercise is to be encouraged, although any form of exercise necessitating strenuous physical effort, or in which the occurrence of an attack might be attended with special danger, e.g., swimming, boating, etc., must be vetoed, unless the patient has with him companions who clearly understand the responsibilities which devolve upon them.

The *education* of epileptic children is a question regarding which the physician's advice is often sought. No doubt it is better, when the attacks occur frequently and are severe, to keep the child away from school; indeed, it often happens that the teacher's attitude permits of no option in the matter. It is, however, highly desirable that the epileptic's time should be fully occupied, although all work involving mental strain, such as that required in preparation for an examination, is to be deprecated. Among the lower middle classes the defective education which absence from school implies constitutes a serious handicap in after life. Irregular attendance at school, in association it may be with a degree of mental deficiency dependent on the disease from which he suffers, often brings the epileptic child into competition with his juniors, and this cannot but have a depressing effect upon a sensitive nature. In addition, the undue irritability and passionate tempers often exhibited by these children may prove incompatible with the requisite discipline of a mixed class. It is to be hoped that the time is not far distant when, in the larger towns, special schools or classes will be set apart for sufferers from this malady.

The *selection of a profession or trade* requires careful consideration, and must be decided on general principles. An outdoor occupation is advisable in confirmed cases. Employments which are fraught with danger must be avoided. The admission of epilepsy is, in itself, often sufficient to debar selection altogether apart from the individual's capabilities for the post he seeks.

Regarding the *question of marriage*, it may be said that matrimony will probably produce little alteration in the frequency or severity of the attacks. In cases of the *idiopathic* variety, particularly when there is a history of hereditary transmission, the physician's duty is to urge his patient to avoid matrimony, by emphasizing the probable consequences of procreation. In cases of idiopathic epilepsy, with evidence of inheritance, Gowers remarks that "consideration of the facts suggests that, if there are six children, the chances are against the escape of all from epilepsy, insanity, or imbecility."

5. Drug Treatment.—In order to obtain the best result, it is essential that the physician should have a definite plan on which his line of action is to be conducted. In every case the question arises, what drug, or combination of drugs, will give the best results without, at the same time, affecting the patient's mental or general health. A solution of the problem can be arrived at only by experiment, while it must at the same time be remembered that frequent haphazard alterations in treatment cannot be too strongly condemned. When it has been determined from, it may be, special features of the case, to commence by giving a particular drug or combination of drugs, this should be given a thorough trial before any change is made.

In every case a record of the fits should be registered. A book should be kept by the patient for this purpose, in which are noted the day and hour at which each fit occurs, and any special exciting cause which may be thought to have produced it. In this book, all changes in treatment are to be entered by the physician. Epileptic patients are often taken from one physician to another—how much to the advantage of both if the patient could produce a record of his previous treatment and its effects.

The *salts of bromine* stand out pre-eminently as the most efficacious drugs. True, in some cases the bromides are of little benefit, and in a minority of these, other drugs are occasionally of value. These instances are, however, exceptional. In most cases the bromides, either alone or in combination with other remedies, produce a beneficial effect on both the severity and the frequency of the fits.

The bromides of potassium, sodium, and ammonium are the salts upon which most reliance is placed, authorities differing as to the most effective form; a combination of all three is regarded by some as the most potent method of administration. The bromides of strontium and of camphor are also used to a limited extent, but appear to have no special advantage. Bromide of lithium has been commended where gout is a prominent feature of the case. So far as we are aware, no general superiority of one form over another has been demonstrated, but individual cases are undoubtedly met with in which the exhibition of one combination appears to be associated with special benefit. Perhaps the bromide of potassium is that most generally used, and it is this form we usually prescribe, in the first instance at least.

Dosage.—The amount of bromide and time of day when it should be given must vary in different cases. The treatment should be commenced by giving 10 to 15 gr. twice a day twenty minutes after food, with a double dose at bedtime. It is not advisable to begin at once with a larger dose than this, unless the patient has previously taken the drug, or is under close observation; for occasionally individuals are met with who are peculiarly susceptible to the action of these salts. When nocturnal attacks alone occur, 25 gr., shortly before bedtime, is sometimes sufficient to produce arrest. A very common time for the occurrence of fits is in the morning, immediately after the patient rises. When this peculiarity is pronounced, a dose of bromide may be given with advantage soon after the patient awakens. The quantity of the drug should be gradually increased until the maximum dose is attained which the patient can take without deteriorating his general or mental health. Most authorities are agreed, however, that there is little advantage in increasing the dose to more than 90 gr. in the twenty-four hours.

There are two *disadvantages associated with the bromide salts*. An acne rash is apt to be produced. It has been claimed that bromide of strontium possesses special virtues in avoiding this complication, but the evidence adduced does not appear to be convincing. Experience has shown that the addition of 2 min. of liquor potassii arsenitis to a 20-gr. dose of bromide is usually effective in preventing the development of acne. Arsenic taken over a long period of time

even in very small doses, unfortunately tends to cause pigmentation of the skin. A 10-gr. dose of salol at bedtime is also said to lessen the tendency to bromide acne. Another disadvantage of the bromides is their blunting effect on the mental faculties. This, however, is seldom seen unless very large doses are given, and the dulling of the intellect so common in epilepsy is more often a direct consequence of the disease than of the remedy.

If complete cessation of the fits follows the exhibition of the bromides, the treatment should be on no account altered; on the other hand, where no improvement follows, other remedies must be tried. When there is distinct improvement up to a certain point, as shown by diminution in the frequency and severity of the attacks, a corresponding dose of sodium, ammonium, or strontium bromide may be substituted, in the hope of producing still further benefit.

Having obtained the maximum effect of the bromides, if the fits still continue, it may be found that the addition of some of the remedies referred to later will be beneficial. The dose of the new remedy may be increased, or, if there is no noticeable improvement, another drug may be substituted, the quantity of bromide remaining unchanged. In this way it is often possible to arrive at some opinion as to the drug or combination of drugs, and their dosage, most suitable in any given case, although it must be admitted that relapses due to undetected causes are frequent sources of difficulty in arriving at definite conclusions.

Amongst the numerous *drugs other than the bromides* which have been recommended, the writer agrees with those who attribute a high place to borax. Borate of soda was first introduced by Sir William Gowers in the treatment of this disease. Occasionally, when the bromides fail, borax is of the greatest value, particularly perhaps where *petit mal* occupies a prominent place in the clinical picture. Borax may be given alone or in combination with the bromides, beginning with doses of 5 gr., three times a day, and gradually increased. Gastro-intestinal symptoms are occasionally set up by borax, and its prolonged administration may be followed by psoriasis.

Digitalis, when given with the bromides, is sometimes attended by benefit distinctly in excess of that obtained from the latter salts alone, especially, it is affirmed, when there is any cardiac complication.

Zinc oxide is of undoubted value in certain cases, more especially in the treatment of *petit mal*. The drug is best administered in pill form in doses of $2\frac{1}{2}$ gr. two or three times a day. The dose may be increased to 5 gr. or even more, but is to be reduced if it produces sickness.

Atropine (gr. $\frac{1}{200}$ to gr. $\frac{1}{125}$) is recommended by Oppenheim.

Belladonna (5 to 10 min. of the tincture) and the nitrites, given in the form of spirit of nitroglycerin (1 to 2 min.), appear occasionally to be of some use when added to the bromides.

Potassium iodide may be of the greatest service where the disease is dependent on syphilis, and is of occasional use in the epilepsies of later life associated with cerebral arteriosclerosis, which so rarely yield to bromide treatment.

A host of other remedies, to which we need not refer, have been from time to time recommended. A serum treatment has been introduced by Ceni, but its value has not been established.

Finally, if treatment is to be attended with success, the *remedies prescribed must be administered with punctilious regularity and over an extended period*. Failure to carry out these essentials is one of the chief reasons why disappointing results are so common. The patient should be most emphatically given to understand that unless he adheres rigorously to these particulars, the prospect of cure is minimized. Indeed, it is advisable in the majority of cases to throw this responsibility upon his relatives. The treatment must be continued until

at least two years have elapsed during which time no fit has occurred, although during the second twelve months the dose may be greatly reduced. Any intercurrent illness must interfere with the administration of the remedies only in most exceptional circumstances.

Whenever there is an increase in the number or severity of the attacks, a most careful examination should be undertaken with the object of ascertaining, if possible, the cause of the relapse. Indeed, it is advisable in every case to make a very thorough study of the case at definite intervals, in order to make sure that no therapeutic indications have escaped detection.

With regard to the "*cure*" of *idiopathic epilepsy*, it is interesting to note that Dr. Aldren Turner found, among 147 cases which had been under observation for at least nine years after the disease had become definitely established, 15 (10·2 per cent) in which the fits had been arrested for nine years or more. He found that in 50 per cent of the cases in which the disease was arrested, the arrest had taken place within one year of the commencement of systematic treatment.

6. Surgical Treatment.—The surgeon's aid is seldom required in the treatment of idiopathic epilepsy. In rare cases, it is true, his help may be solicited to perform a circumcision, or to remove a polypus or foreign body from the aural or nasal cavities. Very exceptionally, in cases in which the involvement of a nerve in the scar of an old wound has been shown to be directly related to the epileptic state, excision of the scar or stretching of the nerve has resulted in cure. To such operations as ocular tenotomies, castration, and ligature of the vertebral arteries, it is unnecessary to refer. Excision of the sympathetic trunks in the neck is unjustifiable. Opening the skull with the hypothetical object of relieving intracranial pressure, in cases of idiopathic epilepsy, is an operative procedure which now has few, if any, adherents. The removal of a small area of cortex, in cases in which the fits commence with a localized motor aura, has not been followed by permanent results. It is to be remembered, in this connection, that any operation may be temporarily followed by cessation of the fits, just as after an acute illness, after an injury, or during pregnancy the attacks sometimes remain in abeyance for many months. This circumstance must always be borne in mind in judging of the effects of surgical intervention.

The above remarks do not apply with equal force to those cases in which the *epilepsy is of traumatic origin*. For instance, when there is a scar over the motor cortex corresponding in situation to the area from which a localized spasm initiating the fit proceeds, and particularly when there is a depression in the bone, operation and excision of the scar is indicated. But it must be remembered that the removal of the local source of irritation is not always synonymous with cure; for in cases of long standing the cerebral cortex may acquire the epileptic habit of spontaneous discharge.

In a case in which there has been a definite injury to the head, and in which the initial discharge does not correspond to the site of the wound, the prospect of cure by operation is much more gloomy. If the local discharge remains constant, the fits obstinately resist medicinal treatment, and the patient's mental condition is deteriorating, excision of the discharging area may be undertaken. When the fits do not commence with a constant local spasm, even if there is definite evidence of cranial injury, the outlook is still worse. Worst of all are those cases in which the attacks are general and have persisted over a long period; in these cases the hope of permanent benefit by local operation is almost nil.

The operative treatment of Jacksonian attacks associated with intracranial new growths and meningeal hæmorrhage is referred to in the articles dealing with these subjects.

7. The Colony System.—The purpose of the epileptic colony or township is to provide education and employment for the sane epileptic. The child receives an education according to his mental capacity. Later, he learns some trade or occupation which may prove of use in after life if his condition improves, and which serves at least to keep him employed and interested. His self-respect is raised and his interest in life aroused when he sees that he is capable of leading a useful existence and is no longer a burden on his relatives; and, lastly, he is living a regular life in the open air, free from excitement and worry, a life which is specially adapted to the treatment of his affection.

A study of the results of treatment shows the advantage of this method. In the majority of cases the fits are reduced in number and severity, and the mental state is improved, while a small percentage of cases is discharged cured.

Edwin Bramwell.

[The State care of epileptics has been much neglected in this country. According to Solenberger they number some 160,000, with provision for only about 5,000 in separate institutions. In most of the states epileptics are cared for in institutions for the insane and feeble-minded or in county almshouses. There is great need for agricultural colonies.]

The following is a partial list of institutions provided, or projected, for the care of epileptics:—

- Connecticut: An institution near Mansfield Depot.
- Idaho: Money has been appropriated, and a site selected, for an institution.
- Illinois: Plans are under way for institutions at Anna and at Kankakee.
- Indiana: The Indiana Village for Epileptics at New Castle.
- Kansas: State Hospital for Epileptics at Parsons.
- Massachusetts: Monson State Hospital at Palmer. A children's colony is in successful operation.
- Michigan: Home for Feeble-minded and Epileptics at Lapeer.
- Minnesota: School for Feeble-minded and Epileptics at Fairbault.
- Missouri: The Missouri Colony for the Feeble-minded and Epileptic at Marshall.
- The Emmaus Asylums for Epileptics at Marthasville and at St. Charles.
- New Jersey: The New Jersey State Village for Epileptics at Skillman.
- New York: Letchworth, The Letchworth Village for Epileptics and the Feeble-minded.
- Sonyea, The Craig Colony for Epileptics.
- Ohio: The Ohio Hospital for Epileptics at Gallipolis.
- A school for epileptics has been provided in Cleveland.
- Pennsylvania: Passavant Memorial Homes for the Care of Epileptics at Rochester.
- Eastern Pennsylvania State Institution for the Feeble-minded and Epileptic at Spring City.
- Texas: Colony for Epileptics at Abilene.
- Virginia: The Virginia State Epileptic Colony near Lynchburg.]

EPIPHORA.—(See LACHRYMAL APPARATUS, DISEASES OF.)

EPISCLERITIS.—This disease is peculiarly prone to recur, and is met with most frequently in patients with a rheumatic or gouty diathesis, and with syphilis; also in subjects of pyorrhœa alveolaris and other conditions which may give rise to a general toxæmia.

TREATMENT must be both local and general.

Local Treatment.—Protection of the eye, hot boracic bathing, and atropine, 2 gr. to the ounce, are especially indicated. Pain is often extremely severe, and is best relieved by two or three leeches to the temple and heat constantly applied to the eye, with hot bathing, repeated fomentations, or the muff-warmer (see IRITIS). In the more chronic cases with little pain, ung. hydrarg. oxid. flav., 1 per cent, may be useful, combined with gentle massage over the lid. Application of the constant current and scarification of the nodule have been advocated.

General Treatment.—A brisk purge should be given at the commencement of the attack, and care taken to procure a free daily action of the bowels. The diet must be carefully regulated and stimulants avoided. Diaphoresis induced by the hot pack, fortified if necessary by an injection of pilocarpine nitrate $\frac{1}{15}$ to $\frac{1}{2}$ gr., will be found invaluable, cutting short the attack and relieving pain. Internally acetyl-salicylic acid, salicylate of soda, and iodides often prove beneficial. Occasionally the pain is so intense that it may be necessary to give subcutaneous injections of morphia. If syphilis is the cause, it must be treated energetically. When pyorrhœa exists, it should meet with scrupulous attention at the hands of a dentist who realizes its importance. *Ilbert Hancock.*

(Revised by W. T. Lister.)

EPISTAXIS.—Bleeding at the nose may be due to general or local causes, and before attempting to arrest it, it is necessary to determine the cause of the trouble and its point of origin.

When due to some *constitutional disturbance* or severe organic disease, epistaxis is frequently beneficial, and unless the loss of blood threatens to become excessive no attempt should be made to stop it. Thus bleeding may be beneficial in some chronic diseases of the heart and lungs, also in certain acute diseases, such as acute bronchitis. It may relieve the strain of excessively high blood-pressure resulting from over-exertion, excitement, anger, or other emotional causes, and thus may possibly ward off an attack of apoplexy or prevent heart-strain. If, however, the bleeding is excessive, simple measures may be adopted to stop it. The patient should lie down quietly, and the face should be sponged with cold water, or a handkerchief dipped in cold water should be laid across the nose. The water should be iced if possible, and the patient may be encouraged to suck ice. If the bleeding is arrested, the patient should remain quiet for a few hours, avoid exertion, and take all food cold, with no stimulants. If the bleeding continues and is not checked by the application of cold, it will generally be necessary to pack the nose. If it is found that the bleeding comes from the anterior part of the nasal septum, it is sufficient to pack the anterior part of the nose with a plug of wool or gauze, and thus to bring direct pressure to bear upon the part. If then the exact source of the bleeding can be determined, cocaine and adrenalin should be applied, and the bleeding spots sealed by the application of the electric cautery at a dull red heat. If there is no indication of the source of the bleeding, but it appears to be coming from far back or high up in the nose, the entire nasal cavity should be packed. A simple method is as follows: The left forefinger is passed through the mouth into the posterior nares, a strip of gauze is passed through the anterior nares until it impinges on the finger, and successive strips are introduced until the whole nose is packed tightly from behind forward, the finger in the post-nasal space preventing the gauze escaping from the posterior nares. A better and more comfortable method, when available, is to introduce into the nose a thin rubber bag, such as a Howard's nasal bag, and to inflate it when in position. The packing, or rubber bag, should be removed within twenty-four hours, and the nose gently irrigated with a weak antiseptic lotion to avoid sepsis. Removal of the gauze may set up fresh bleeding; this is not so likely to happen with the rubber bag, which is deflated before it is removed, and does not adhere to the tissues. For the next day or two the patient must remain quiet, avoid blowing the nose, take all food cold, and avoid stimulants.

When hæmorrhage from the nose is the result of a *gross lesion*, such as ulceration or malignant or other tumour, and the bleeding is not arrested by the local application of cold, it will generally be necessary to pack the nose with strips of gauze as above described. Subsequently the cause can be dealt with.

In the commonest form of epistaxis, in which the bleeding takes place from small vessels on the anterior part of the septum, and is due entirely to local causes, local treatment alone should be adopted. The trouble is due to the so-called *anterior rhinitis sicca*, and the bleeding is the result of forcibly detaching the small crusts, which adhere closely to the nasal mucous membrane, by picking or violently blowing the nose. The first essential is the removal of the cause. The local condition should be treated by the frequent application of a mild ointment, such as weak boracic ointment or plain lanolin. Picking the nose should be prohibited. These measures alone frequently effect a cure. If they fail, a solution of cocaine and epinephrin should be applied, the bleeding spots should be sealed, and all the small varicose vessels obliterated by a few touches with the red-hot cautery. The affected part of the septum should be frequently smeared with ointment to prevent crusts forming until healing is complete. If at any time severe hæmorrhage occur, it may be arrested immediately by passing a strip of gauze or wool into the affected nostril, and bringing direct pressure to bear upon the part by compressing the nostrils with the fingers.

In a few rare cases, where the mucous membrane of the anterior part of the septum, and more rarely of other parts of the nose, is red, velvety, almost naevoid in appearance, and readily bleeds on touching, it is necessary to excise the whole of the affected part.

H. Lambert Lack.

EPULIS.—(See JAW, TUMOURS OF.)

ERUCTATION, NERVOUS, is not altogether under the control of the patient, but is temporarily stopped by swallowing anything, such as a little water, and no doubt much can be effected by the patient if she will do her best to break the habit. Pressure upon the epigastrium sometimes relieves it. The treatment is for the general neurotic condition: change of air, general massage, isolation, and a Weir-Mitchell course. Chewing rhubarb or ginger root or charcoal biscuits, by inducing swallowing, affords relief. Medicinal remedies may be tried, such as the following mixture:—

R Potassii Bromidi	gr x	Aquæ Camphoræ	q.s. ad ʒj
Tincturæ Valerianæ Ammon.	℥xxx		

Two tablespoonfuls three times a day.

Robert Saundby.

ERYSIPELAS is an infective condition of the skin or subcutaneous tissues, due to a peculiar variety of streptococcus. It is customary to consider certain special varieties.

1. **Erysipelas Proper**, the infection being confined to the lymphatic spaces immediately beneath the epidermis, a form usually unaccompanied by swelling of the tissues except in such situations as the scrotum and the eyelids.

2. **A Superficial Form of Cellulitis**, indicated by swelling and redness of the part.

3. **Deep Cellulitis**, which is an infection of the subfascial layers. Only as the process tracks towards the surface does the skin become red. There are, however, considerable pain and swelling, and the whole part has a brawny, indurated feeling.

The last two varieties may be associated with a large amount of tissue destruction, owing to the sloughing of the skin stretched over the inflammatory exudate.

TREATMENT.—As these infections are more liable to occur in patients whose constitution is unsound, either from glycosuria or albuminuria, a careful

examination of the urine must be made. As a routine the bowels should be opened by a brisk purge; subsequently, stimulants and tonics may be administered, quinine and iron being most useful. A rigor is often the first symptom of the superficial variety, and in many cases—especially in children—the constitutional symptoms are most severe. The temperature may rise to 104° or 105° .

Local treatment consists in applying lotions or protective dressings, leaving the disease to run its course, a form of treatment suited to mild cases; but any unhealthy focus from which the infection has arisen should be actively treated with pure carbolic acid. One of the best applications in mild forms of the disease is a lead and opium wash (N.F.), or, if preferred, gauze wrung out of 1-60 carbolic may be substituted. Ichthyol has been used in the form of a paint with much success.

If the attack is a severe one, and if the part affected is suitable for more active treatment, the weak tincture of iodine or a strong solution of silver nitrate may be painted $\frac{1}{2}$ to 1 inch away from the red, sharply-defined edge. The object of this treatment is to excite a protective leucocytosis which will be able to destroy the infection or the organisms as they reach this protected zone. Kraske scarifies the area round the erysipelatous rash with a fine knife in order to produce the same effect, and it is said that a more energetic and satisfactory reaction is produced by this method.

Incisions are not as a rule required in this variety; but when the scrotum or the eyelids are attacked, the loose cellular tissues become swollen and œdematous, and the knife may be used with advantage. Minute punctures only should be made. In alcoholics, erysipelas may attack the mouth and pharynx, an exceedingly dangerous situation, since there is considerable risk of œdema of the glottis supervening. Erysipelas of the face and scalp may give rise to serious intracranial complications, since the infective process may spread along the numerous channels of communication into the cranial cavity.

Treatment of the other cellulitic varieties must be conducted along more rigorous lines. In a few cases it may be advisable to try the effects of rest and moist antiseptic dressings for twenty-four hours, but, with this exception, the sooner incisions are made into the inflamed area the better. When active treatment is delayed, the inflammatory process tends to burrow along the fascial planes, and deep-seated abscesses will form. The incisions should be free and numerous, with a due regard to the position of important structures, and they should extend, in the case of the deep cellulitis, right through the deep fascia. Drainage tubes must be employed in those cases where there is a localization of the pus.

After-treatment will consist in supporting the patient's strength, so that he may be able to neutralize the toxins elaborated in the affected region. Alcohol may be required, and iron, quinine, nux vomica, and arsenic will be of service. The part should be dressed with moist antiseptic dressing. In many cases constant irrigation with weak carbolic (1-200) or boracic acid is indicated, or as an alternative, if a limb is affected, it may be immersed in a bath of the same antiseptic. It is essential to see that only a very weak solution is used, as the continued application of strong antiseptics is very injurious to the tissues, and may lead to poisoning.* As soon as the acute inflammatory phenomena have subsided, massage and passive movements should be cautiously undertaken, so as to prevent undue fixation.

The greatest care must be taken that the infection from these cases is not conveyed to others, especially to surgical or midwifery patients. Cases of erysipelas and cellulitis should be isolated.

W. H. Clayton-Greene.

* The application of carbolic solution to the extremities may be followed by gangrene.—AMERICAN EDITOR.

ERYTHEMA.

Erythema Induratum Scrofulosorum.—The characteristic lesions of this disease on the lower part of the leg posteriorly have, in the past, generally been treated by rest and strapping, along with general tonics. These latter will probably maintain their place. But since the time the writer first used *x* rays in this disease, he has not found it necessary to insist upon the lying-up previously required. Under repeated exposures to the rays, the ulcers heal up and the induration disappears, even although the patient continues at work so obviously unsuited to rest as that of a message girl. In some cases nodules break down under the treatment, but this should not be taken as a contra-indication, for the healing process soon sets in, and goes on satisfactorily. We have recently used powdered uranium nitrate with such excellent results, in a case which had proved obstinate to *x*-ray treatment, as to encourage further experiment.

Erythema Iris.—There is no satisfactory routine treatment for this disease. Indeed its invariable tendency to recurrence shows as much. The lesions should be protected from further injury by some harmless application such as zinc ointment. The favourite boric ointment should be avoided, as it often causes great pain. The salicyl compounds are occasionally useful, but not often, and general tonics, such as quinine and the like, may be tried. Most, however, can be done by keeping the patient in the best of health, and encouraging him by telling him that the attacks will eventually cease.

Erythema Multiforme.—It is quite impossible to indicate with any definiteness how this protean condition can be successfully treated. The manifestations in the skin may be produced by a whole series of different causes, which must be sought for and eradicated. It may, however, be said generally that erythema multiforme is the expression of some form of intoxication, and that the search for some toxin should be thorough. In many cases it is obvious some dietetic poison can be held directly answerable for the eruption, in others it is probable that putrefactive changes in the intestines are the source of the poison; and very strict attention to diet, and the administration of intestinal antiseptics, will often result in the disappearance of the eruption.

Empirically, certain drugs are given. Ichthyol, quinine, sulphur, iodide of potassium, and ergot have been recommended. Patients who suffer from these last two forms of erythema, both almost certainly toxic in origin, derive as a rule great benefit from the drinking of large quantities of water. Ordinary water does quite well, but many patients can be persuaded to drink larger quantities if the water has a name attached to it.

Erythema Nodosum.—See RHEUMATISM.

Norman Walker.

ERYTHROMELALGIA.—The treatment of this rare condition is very unsatisfactory. Rest in the recumbent position, with the limb raised, is the first essential. It should be carried out for some weeks, or even months. It may be combined with gentle massage and cold applications locally. As excessive smoking is believed to aggravate the condition, the use of tobacco should be stopped. Electrical treatment is sometimes useful, and in one case recovery is said to have taken place after twenty applications of faradism. Drugs are of little help. It is sometimes necessary to use morphia in order to afford relief; but there is a great danger of establishing a habit, although a cure is reported in one instance after the hypodermic injection of morphia and atropine into the side of the foot night and morning for three weeks. Iodides should be given in all cases with a syphilitic history.

Search should be made for any possible causes of pressure on vessels or nerves (e.g., aneurysm, tumour, inflammatory thickening, cervical rib, etc.). Stretching

of the posterior tibial nerve has sometimes been carried out with advantage ; and in intractable cases amputation may have to be considered.

Robert Hutchison.

ETHMOIDITIS.—(See NOSE, ACCESSORY SINUSES OF.)

EYE, INJURIES OF.—We shall consider the treatment of ocular injuries under two main headings : (I) Injuries without perforation of the globe ; (II) Injuries with perforation.

I.—INJURIES WITHOUT PERFORATION.

In this group will be included :—(1) Contusions, with consequent internal injuries : (a) Iridodialysis, and paralysis or rupture of the sphincter of the iris ; (b) Paralysis of the ciliary muscle ; (c) Iritis and cyclitis (see IRITIS) ; (d) Dislocation of the lens, and cataract ; (e) Hæmorrhage into the anterior chamber or vitreous ; (f) Rupture of the sclerotic ; (g) Detachment of the retina and retinitis (see ophthalmic text-books). (2) Abrasions of the cornea. (3) Foreign bodies in cornea or sclerotic. (4) Wounds of cornea, conjunctiva, or sclerotic.

1. **Contusions of the Eye** may cause a great variety of intra-ocular changes, many of them very severe. A guarded prognosis should be given till a complete examination (both with the ophthalmoscope and by testing the sight) can be made.

The patient must be kept at rest, and the eyes protected from the light by dark glasses. If there be pain or hæmorrhage, cold compresses should be used for the first twenty-four hours, but after the risk of further hæmorrhage taking place is over (generally in forty-eight hours), hot applications should be substituted to help the absorption of the blood. Weak atropine drops (1 or 2 gr. to the ounce) should be used till all danger of inflammation has passed. If iritis or cyclitis supervenes, it must be treated energetically (see IRITIS).

Iridodialysis.—Nothing further than the above treatment is necessary.

Paralysis or Rupture of the Sphincter Iridis, or Paralysis of the Ciliary Muscle.—In none of these conditions is atropine advisable unless indicated by other complications. Some recommend atropine to be used in the other eye to prevent consensual action.

Dislocation of Lens.—With dislocation of the lens the refraction is always changed. If the eye quiets down and the lens remains behind the pupil, the eye as a rule becomes myopic, and a correcting lens may be of service ; after dislocation into the vitreous, a strong convex lens may improve vision. A lens dislocated into the anterior chamber should be removed. *Secondary Glaucoma* may occur (see GLAUCOMA), or *Cataract* may supervene (see CATARACT).

Intra-ocular Hæmorrhages.—Rest, dark glasses, cold compresses for twenty-four hours, followed by hot applications, weak atropine drops (1 or 2 gr. to the ounce) three times a day.

If the hæmorrhage causes rise of tension, the patient must be kept in bed, two leeches be applied to the temple, and a brisk purge given ; eserine should not be used, and weak atropine may be tried tentatively, but if the tension does not come down, atropine should be withheld.

Rupture of the Sclerotic.—(a) Without laceration of the conjunctiva. The above treatment is all that can be given—rest, leeches, atropine, etc.—the main indication being the treatment of the consequent traumatic iridocyclitis. If the lens be dislocated under the conjunctiva, it should be left alone, when it will probably become absorbed. (b) If laceration of the conjunctiva has occurred, in addition to the above treatment the eye should be carefully washed out and dressed regularly with the strictest antiseptic precautions. In either

case, if the eye is not quieting down in a fortnight's time, or has become a useless organ, it should be removed. In cases where the eye is clearly destroyed at the time of the injury, it should be enucleated at once.

2. Abrasions of the Cornea.*—The conjunctival sac should be washed out with warm boracic lotion, a little atropine ointment (1 gr. to the ounce) inserted between the lids, and the eye kept tied up till the surface has healed. If there is photophobia, a shade may be worn over the good eye, or dark glasses be used, a pad of wool sufficiently thick to keep the lid shut being placed between the glass and the bad eye.

3. Foreign Body in the Cornea or Sclerotic.—After anæsthetizing the surface with a 2 per cent solution of cocaine, the foreign body is removed with a sterilized needle or spud, care being taken to injure the surrounding tissue as little as possible. (If pieces of hot iron from an emery wheel are embedded in the cornea, the ring of brown stain usually met with should also be removed.)

When the foreign body is so deeply embedded in the cornea that there is danger of its being pushed into the anterior chamber, a broad needle is passed into the cornea behind the foreign body, and the latter can then be removed without risk. If it is projecting into the anterior chamber, the broad needle must be passed into the chamber behind the foreign body, and kept pressed up against the back of the cornea till it is removed.

After-treatment.—The conjunctival sac should be well washed out with warm boracic lotion, atropine drops (2 gr. to the ounce) instilled, and a pad (cyanide gamgee) and bandage worn until the eye is quiet and the surface healed. If irritation persist, and if any signs of iritis occur, the use of atropine must be continued till the eye has completely quieted down.

Should the cornea become infiltrated, see CORNEA, DISEASES OF.

4. Wounds (without Perforation) of Cornea, Conjunctiva, and Sclerotic.—Uncomplicated wounds of the cornea are treated like abrasions, viz., by washing out the conjunctival sac, and the instillation of atropine, the eye being kept bandaged till the surface has healed. Wounds of the conjunctiva heal readily. If laceration has taken place, the cut edges should be sutured with fine sterilized silk, and the eye tied up till healing is complete. Wounds of sclerotic: if the wound gapes, the edges should be sutured (*vide infra*).

II.—INJURIES WITH PERFORATION.

Penetrating Wounds are always of extreme importance, not only from damage done by the injury itself and by the consequent inflammation, but from the possible danger to the other eye of sympathetic ophthalmitis. In treating penetrating wounds, therefore, we have to find out: (1) How far the injured eye is likely to be a useful visual organ; and (2) How far it is a menace to its fellow. In answering these questions five considerations are very important.

i. *Does the Eye contain a Foreign Body?*—If so, it not only will almost certainly be lost from iridocyclitis, but it is a danger to its fellow. Therefore, as a general rule, such an eye must have the foreign body removed, or be itself removed. (N.B.—A foreign body is tolerated best in the lens. Of foreign substances found in eyes, glass seems to be the least irritating; while of metals, iron and copper, especially the latter, are very irritating.)

ii. *Has Septic Matter been introduced?*—If so, the eye will in all probability be lost from iridocyclitis or panophthalmitis. Chronic iridocyclitis following a penetrating injury is very liable to cause sympathetic trouble in the other eye.

* The detection of an abrasion is greatly facilitated by the use of a solution of fluorescein 8 gr., sodium bicarbonate 12 gr., to the ounce. One drop is instilled into the eye, followed by a few drops of boracic lotion or solution of cocaine. The abraded surface stains green.

Panophthalmitis, while causing complete loss of the eye, does not as a rule cause any sympathetic mischief.

iii. *Is the Lens injured?*—This is discovered on careful examination by oblique illumination and with the ophthalmoscope after dilatation of the pupil.

Traumatic cataract will almost certainly follow, and hence binocular vision will be lost: for however well the eye quiets down and the opaque lens is absorbed or artificially removed, an eye supplemented by a strong convex glass, in place of its own lens, will practically never work with its uninjured fellow. On the other hand, though binocular vision is lost, an eye without a lens is very useful, in that it enlarges the field of vision on a side which would otherwise be blind, and thus gives invaluable assistance in crossing streets, driving, etc.

If the wound in both lens and cornea be large, the lens capsule is very likely to be entangled in the corneal wound, and as this cannot be recognized directly after the injury because of the transparency of the capsule, it cannot be removed. It is now generally accepted that entanglement of the lens capsule in the wound is nearly as dangerous in its liability to cause sympathetic ophthalmitis as entanglement of uveal tissue (*vide infra*).

An eye whose lens has been injured takes a long time to quiet down, since it has the double work of recovery from the trauma and the absorption of the lens.

From these three considerations we see that though a reasonable attempt should be made to save an eye with an injured lens, yet it is not justifiable to run the same risk as in trying to save one with an uninjured lens.

iv. *Is there Prolapse of Iris, Ciliary Body, or Choroid?*—A protrusion of any part of the uveal tract on the surface of the eye, since it is liable to direct infection from without, is very dangerous from the point of view both of sympathetic ophthalmitis and panophthalmitis. The more completely these protrusions can be removed the greater is the chance of recovery. Hence, prolapse of the iris, being more easily separated and excised, is less serious than prolapse of the ciliary body, where freeing of the wound from all entanglements is seldom possible. A wound in the ciliary region with prolapse of the ciliary body is the most dangerous of all penetrating injuries. A prolapse which cannot be removed, even if the eye quiet down after the injury, is always a possible source of danger, and must be looked upon as a serious condition.

v. *Is there Displacement of the Contents of the Eye?*—When there is displacement or loss of the lens, prolapse of retina, etc., in addition to the external wound, enucleation should be performed at once; but if there appears any chance of retaining a useful organ, tentative treatment may be tried (*vide infra*).

Having given the main indications for forming an opinion as to whether the injured eye is likely to be useful or useless, safe or dangerous, we will consider the treatment of these various complications.

Foreign Body in the Eye.—The presence of a foreign body may be surmised from:—

a. *The History.* What struck the eye? What was the patient doing when the eye was struck? (E.g., if the patient was hammering or chopping, and something small, which was not afterwards found, struck the eye, it is very possible a small chip of metal entered the eye.)

b. *The Appearance of the Eye.*—By careful oblique illumination a minute track may be discovered through the cornea or lens, or a small gap seen in the iris; or again, the ophthalmoscope may reveal a track through the lens or vitreous, a scar on the retina, or even the foreign body itself.

c. *X-ray Photograph.*—This may show the presence of a foreign body.

d. *Use of Haab's Magnet.* If pain be experienced on bringing the eye close to one of these powerful magnets, there is strong evidence of the presence of a piece of iron.

If a foreign body is visible it must be removed, either with the magnet or forceps, according to its nature. If invisible, it must be carefully localized by means of *x*-ray photographs. If it is a chip of iron it should be removed with a strong electro-magnet; if of some non-magnetic material, its removal with forceps should be attempted, though the chance of success is small.

For after-treatment, *vide infra*.

Septic Wounds.—Here little can be done to save the eye. If panophthalmitis has set in, evisceration of the globe should be performed without delay. The cornea is first removed, and the contents of the globe are then completely scooped out, the sclerotic being left to shrink up. This is a tedious process, lasting fourteen days or more, so that some prefer enucleation of the globe. But the danger of meningitis after enucleating a suppurating eye is a very real one, being brought about by infection of the vaginal sheath of the nerve by the scissors with pus which has escaped from the eye. If enucleation be preferred, evisceration is first done, followed by very thorough irrigation of the empty sclerotic and conjunctival sac; the sclerotic is then stuffed with gauze in order to make its enucleation more easy, which, after a second irrigation of the conjunctival sac, is then performed. A drainage tube should be used, and inserted right to the back of the orbit, to prevent any discharge collecting round the cut end of the optic nerve.

When only the anterior chamber is infected and contains pus, and there is no sign of pus in the vitreous, an attempt may be made to disinfect the eye by washing out the anterior chamber with normal saline, chlorine water, or hydrogen peroxide. (For after-treatment, *vide infra*.) It is, however, seldom successful in preventing panophthalmitis, and the eye has usually to be excised or eviscerated.

If chronic iridocyclitis occurs, and does not subside at the end of ten days or a fortnight, the eye should be excised, especially if the cornea has become hazy, the iris muddy, and spots of keratitis punctata are seen on the back of the cornea.

In cases where there is no entanglement of uveal tissue or lens capsule, and the cornea and iris remain bright, we may wait a little longer; but three weeks must be taken as a limit beyond which it is unsafe to temporize.

Wounds of the Lens.—*Clean Punctured Wounds* of the lens often give rise to no trouble beyond the traumatic cataract which almost invariably follows any injury of the lens capsule.

Atropine drops should be given to keep the pupil dilated, to allow soft lens matter to come forward into the anterior chamber, and to prevent the formation of posterior synechiæ. If iridocyclitis set in, it must be treated in the ordinary way, with rest, atropine, hot bathing, etc. If soft lens matter collect in the anterior chamber and cause increased tension, it must be let out by a curette evacuation.

Large Wounds of both Cornea and Lens as a rule do badly; the eye usually does not quiet down, and has to be removed. The wound must be freed from all entanglements or prolapse of uveal tissue or lens capsule as far as possible, any soft lens matter which has collected in the anterior chamber should be let out, and an attempt made to save the eye. For after-treatment, *vide infra*.

In all wounds of the lens the danger of entanglements of lens capsule must not be forgotten (see above), and if the inflammation is not subsiding in two weeks' time, enucleation is the safest course. At times the eye does well up to a certain point, the cornea and iris remaining bright, but still some irritability and congestion remain; in these cases, if a tag of capsule is seen adherent to the wound, division of this will sometimes allow the eye to recover completely.

Prolapse of Uveal Tissue.—The chief danger being infection of the uveal tract from without, through the prolapse itself, our main object must be—

(1) Either to remove the prolapse so completely that no trace of uveal tissue remains either on the surface, included in the wound, or even adherent to the back of the wound (the first is the most, the last is the least, dangerous condition); or (2) If it is impossible to remove the prolapse, we must endeavour to separate that portion of the uveal tissue incarcerated in the wound from the rest of the uveal tract.

Prolapse of Iris.—*a.* In cases seen directly after the injury, cocaine is instilled or a general anæsthetic given, according to the character of the patient; the conjunctival sac is carefully washed out with boracic lotion, all lymph adherent to the wound being thoroughly removed; the prolapse is picked up with forceps, gently freed all round from the lips of the wound with the repositor, and then drawn out as far as it will come, and cut off close to the cornea. We hope by this means that the iris, after being cut, will retract free from the wound. (In drawing out the iris a second pair of forceps is often of great use to grasp the iris close to the cornea and pull it out still further, after the first pair has done all it can.) Any remaining tags of iris are removed or replaced.

If forceps have to be introduced into the anterior chamber to remove tags of iris, and the lens is not already injured, great care must be exercised lest the lens capsule be divided accidentally with the forceps, and a traumatic cataract supervene—a most disastrous accident.

b. Four days after an injury such firm adhesions will have taken place that a prolapse cannot be freed. If the adhesion be small and not close to the periphery, it may be divided by a cutting needle introduced into the anterior chamber. If near the periphery, a linear knife may be passed across the anterior chamber and the base of the prolapse cut across, followed by an iridectomy, so as to free the adherent portion of the iris from its attachments. For after-treatment, *vide infra*.

Entanglements of Iris.—Where the iris is only entangled in, or adherent to, the wound, and there is no prolapse on the surface, there is, after the wound has healed, no direct communication from the surface to the uveal tract. These cases are therefore much less serious than cases of prolapse. On the other hand, it is well known that though wounds with entanglements often quiet down well, yet they do not do this so quickly as wounds with no entanglements or where these have been freed. Hence, as a guiding rule, if at the time of the injury the entanglement can be easily freed, this should be done, either with a cutting needle introduced into the anterior chamber, or by an iridectomy through the wound. If this is impossible, the eye should be treated in the ordinary way, with rest, a pad and bandage, atropine, etc. (*vide infra*), and be given a chance of quieting down. If it does not do this in a fortnight's time, and the pulling of the iris appears to be the only cause of irritation, division of the synechia or iridectomy should be undertaken.

Prolapse of the Ciliary Body and Choroid.—These cases are more dangerous than those with prolapse of iris, because of the difficulty of freeing the prolapse. A prolapse of the ciliary body or choroid which is not obviously infected or lacerated should in recent cases be pushed back, and the sclerotic brought together with sutures (*vide infra*). If, however laceration has taken place, or infection is probable, the prolapse should be drawn out with forceps and excised as in the case of the iris, and the sclerotic sutured. When four or five days have elapsed since the injury, the prolapse cannot be removed, and must therefore be left.

In either case, whether the prolapse has been removed or not, we must fully recognize that we are dealing with a condition the most dangerous of all in its liability to cause sympathetic ophthalmitis. If the other eye is sound, we are not justified in running any serious risk in trying to save its injured fellow, lest

in our endeavour to save the one we lose both. Should the eye, therefore, not begin to improve in a week or ten days, it had better be excised.

Wounds of the Sclerotic.—Where it is thought desirable to try to save an eye with a gaping wound of the sclerotic, with prolapse of ciliary body, choroid, or vitreous, we proceed as follows : After anæsthetizing either locally or generally, the conjunctival sac should be washed out, the uveal tissue pushed back or excised, the vitreous snipped off, and the sclerotic brought together with sutures. These are passed in the following way : We use a double-needed suture of fine sterilized silk, and having grasped the sclerotic firmly with toothed forceps to prevent further loss of vitreous, we pass each needle from within outwards, not quite through the whole thickness of the sclerotic, and then through the cut edge of the conjunctiva, taking care not to include any uveal tissue in the suture or in the lips of the wound. In this way the whole wound is brought firmly together with as many stitches as are necessary.

AFTER-TREATMENT OF PENETRATING WOUNDS.—The conjunctival sac is carefully washed out both before and after any operation that may have been done. Sterilized atropine drops are instilled, or atropine ointment inserted between the lids. Strict asepsis is observed throughout. A pad of cyanide gamgee tissue is used as dressing, and the eye is bandaged. Two leeches are applied to the temple, a purge is given, and absolute rest in bed is enjoined. The eye is dressed daily, and the use of atropine continued till all danger of inflammation is over.

If iridocyclitis supervenes, more energetic treatment must be adopted, viz., atropine three times a day, hot applications, further leeching, light diet, etc. (See IRITIS.)

If the eye quiets down in a fortnight or three weeks, it may be saved ; but if after the first week it gets steadily more red, and especially if the cornea becomes hazy, the iris muddy, and spots of keratitis punctata appear on the back of the cornea, it should then be excised without further delay.

It is usually considered that we are safe from sympathetic mischief for about three weeks after an injury, but symptoms have occurred within ten days, which fact points to the process having begun even earlier ; so that unless there appears to be a good chance of saving a useful eye, we are not justified in postponing excision beyond ten days or a fortnight. Too great a risk must not be run, lest blindness in both eyes be the result.

W. Tindall Lister.

EYELIDS, DISEASES OF.

Meibomian or Tarsal Cyst (Chalazion) is a benign neoplasm identical in structure with granulation tissue. In the earliest stages of these little growths, hot boracic bathing and the use of ung. hydrarg. oxidi-flav., 4 gr. to the ounce, will sometimes lead to their absorption. Failing this, should the tumour prove disfiguring, or cause discomfort, it should be removed by incising and scraping. This may be done under a local anæsthetic or under gas and oxygen. When the cyst is in the tarsus itself and there is little inflammation, cocaine is quite sufficient ; but when the cyst has come forwards between the tarsus and the skin, or when there is much inflammation, it is wiser in sensitive subjects to give a general anæsthetic, and to make sure of removing the tumour thoroughly, than to cause a great deal of pain, to have to desist, and for the tumour to recur. If a local anæsthetic is decided on, after a few drops of 2 per cent cocaine solution have been instilled into the conjunctival sac, the lid must be everted and a few crystals of solid cocaine applied to the conjunctiva immediately over the swelling.* Using a Beer's knife, a free vertical incision should

* Only a very few crystals should be used, and the lid should be kept everted and as dry as possible, to prevent a strong solution passing down the duct into the throat, as alarming symptoms from cocaine poisoning have occurred after too free a use of the solid salt.

now be made, and the granulation tissue removed by a thorough scraping with a small scoop until, on manipulation, no tumour can be felt. It is most important that all this tissue be removed; otherwise the swelling will most certainly recur. Sometimes these growths are exceedingly hard and fibrous, and quite impossible to remove by scraping. They should then be dissected out, either from the conjunctival surface, or, if they project forwards, through the skin of the lid—in the latter case a subcutaneous injection of novocain and adrenalin is useful.

The small marginal chalazia which occur at the border of the lid should be shaved off level with the surface, and scraped.

Occasionally large numbers of chalazia occur, and in successive crops. In such cases treatment by vaccines prepared from the infected cysts is sometimes very efficacious.

Hordeolum (Stye) is an inflammation of the ciliary follicle, and is frequently associated with a lowered state of health or some error of refraction. In its treatment, therefore, the health of the patient must be inquired into, and suitable tonics given. The refraction must also be carefully investigated, and glasses ordered if necessary.

Locally, in the early stages, epilation of the eyelash corresponding to the inflamed follicle, followed by hot boracic bathing and the application of ung. hydrarg. oxidi-flav., 4 gr. to the ounce, will often cut short the attack. If pus develops, a small incision must be made, and hot fomentations be applied until all swelling has subsided. If crops of styes occur, treatment by vaccination is advisable.

Ptoſis, or drooping of the upper lid, may be congenital, paralytic (third nerve or sympathetic), or the result of long-standing inflammation, e.g., trachoma.

Congenital Ptoſis.—Slight cases of this condition require no treatment, but if more than half of the pupil is covered by the lid, an operation is indicated. Of the many plans devised to rectify the deformity, those of Hess, Mules, and Panas give the best results.

Paralytic Ptoſis.—When resulting from paralysis of the third nerve, a course of general treatment directed against the constitutional cause should be carried out. In the slight form resulting from sympathetic paralysis, no local treatment is necessary, as the drooping of the lid is never sufficient to interfere with sight. When due to myasthenia, treatment so far is of no avail.

Inflammatory Ptoſis.—In these cases we must, of course, treat the disease which is giving rise to the deformity.

Epicanthus.—Only in extreme degrees of this congenital abnormality is operative interference justified, for the deformity tends to lessen or disappear with the development of the bridge of the nose. In such extreme cases a vertical ellipse of skin should be excised from the dorsum of the nose.

Blepharitis.—Clinically we meet with two well-defined groups of cases.

1. **Blepharitis Squamosa.**—Characterized by the presence of branny scales along the margin of the lid which, when removed, expose a hyperæmic but not ulcerated surface.

Very frequently some refractive error which causes congestion of the lids is the chief etiological factor, and this should be corrected by suitable glasses; at the same time the general health must be inquired into, and treatment adopted when necessary.

Locally, strict cleanliness, the removal of the scales by the frequent use of an alkaline lotion, e.g., sod. bicarb., 10 gr. to the ounce, and anointing the lid margins night and morning with a mercurial ointment, e.g., ung. hydrarg. oxidi-flav., 4 gr. to the ounce, or ung. hydrarg. nit. dil. (B.P.) is all that is necessary.

2. *Blepharitis Ulcerosa*.—Here the lid margin is covered by firmly adherent yellow crusts which, on removal, expose an ulcerated surface. This is a much more severe form of blepharitis, and may lead to permanent malformation of the lid, or destruction of the ciliary follicles. As in blepharitis squamosa, the general health and refraction must first be carefully investigated. In the severer forms of this disease it is a good plan to commence treatment by epilating the lashes in the affected areas, and after a thorough cleansing and removal of the scales, to paint the lid margin with a solution of silver nitrate, 10 gr. to the ounce, or protargol, 100 gr. to the ounce. Subsequently, frequent bathing with an alkaline lotion and anointing the lid borders with a weak mercurial ointment must be energetically persevered with.

In the worst forms of this disease, when the lids are thickened and rounded, and epiphora from stenosis or eversion of the puncta is a marked symptom, it becomes necessary to slit up the lower canaliculus for the outer two-thirds of its extent.

Entropion, or Inversion of the Eyelids.—*Spasmodic Entropion* of the lower lid is met with most frequently in old people, and is particularly liable to occur if the eye has been bandaged. In the slight cases, it is generally sufficient, after dispensing with the bandage, to evert the lid into its normal position and fix it by means of strapping. Equally good results may be obtained by painting the skin of the lower lid with collodion, or pinching up a horizontal fold of skin and transfixing it with two or three vertical sutures, which are tied and allowed to remain until they cut their way out.

In the severer forms of this condition, the above methods are insufficient, and it becomes necessary to remove a narrow strip of skin and orbicularis muscle. After a subcutaneous injection of novocain and adrenalin, a horizontal fold of skin as near the lid margin as possible is picked up with forceps and excised with a pair of scissors. A fold of the underlying orbicularis muscle is then removed in a similar manner. Sufficient skin and muscle must be removed to prevent any return of the entropion on squeezing the lids at the time of operation, but not so much as to cause any ectropion. A somewhat greater effect can be obtained by removing a small vertical portion of skin and muscle at the outer end of the horizontal incision, thus shortening the lid. After taking care to arrest all hæmorrhage, a few sutures are inserted and the wound is dressed with gauze.

Cicatricial Entropion.—The most common etiological factors in this form of entropion are trachoma and the cicatrization following burns. An operation is necessary to correct the deformity, and one of three procedures is commonly adopted: (1) Restoring the incurved tarsal cartilage to its normal position—Streatfeild's or Burow's operation. (2) Transplantation of the lash-bearing portion of the lid—Arlt-Jaeschke. (3) Removal of the lash-bearing portion of the lid.

Ectropion, or Eversion of the Lid.—*Senile Ectropion*.—In the milder cases of this condition, it is important to direct the patient, when wiping his eye, always to pass the handkerchief from below upwards, and so avoid the lid being still further dragged away from the eyeball. The conjunctiva must be carefully treated with astringents (e.g., guttæ zinci sulph., 1 gr. to the ounce), and the application of silver nitrate, 10 gr. to the ounce, twice weekly. Failing this, an effort may be made to replace the everted lid by the cauterization of the conjunctiva with the actual cautery and slitting the outer two-thirds of the canaliculus. In the severer forms, when the lid is much everted and the exposed conjunctiva redundant and thickened, a more extensive operation is indicated, as Snellen's suture, or Argyll Robertson's or Tweedy's operation.

In *Paralytic Ectropion*, from paralysis of the orbicularis palpebrarum muscle, slitting the canaliculus and removal of the inner wall should first be tried, but will probably prove insufficient; it then becomes necessary to shorten the lower lid by a suitable operation.

Cicatricial Ectropion is the most intractable form of ectropion with which we have to deal, and may result from cicatrization following burns, wounds, cellulitis, lupus, etc.

An operation is always necessary, and the procedure to be adopted must of necessity vary with the amount of destruction of the parts, and often requires much thought and ingenuity.

Ilbert Hancock.

(*Revised by W. T. Lister.*)

FACIAL PARALYSIS (Bell's Palsy).—Treatment varies according to the cause. In syphilitic cases administer mercury and iodide of potassium. Cases due to suppurative conditions of the middle ear, implicating the nerve within the Fallopian aqueduct, must have the area of suppuration promptly treated in order to prevent total destruction of the nerve. In wounds of the face or neck, which have divided the nerve after its exit from the stylomastoid foramen, primary suture of the nerve-trunk must be performed.

By far the commonest, however, is the so-called "rheumatic" variety. In such a case, a fly-blister should be applied over the front of the mastoid process, as nearly as possible over the site of the stylomastoid foramen, and diaphoretic medicines and a smart purge administered, whilst protecting the patient against chills. Sometimes there is considerable pain at the onset of these "rheumatic" cases. This can usually be allayed by antipyrin in 10-gr. doses, repeated if necessary. The time of reappearance of motor power varies according to the severity of the inflammation of the nerve. In any case, until motor power begins to reappear, the paralyzed muscles must be stimulated several times a day with the continuous current, for about a quarter of an hour at a time, in order to maintain their nutrition. This the patient should be taught to do for himself, sitting in front of a mirror, so as to see that the muscles actually contract. The negative pole is stroked gently along the muscles, radiating in different directions forwards from the ear, whilst the positive pole is placed on the back of the neck or some other "indifferent" spot. The galvanic current should be moderate in strength, just enough to produce distinct muscular contraction. The patient must persevere scrupulously with this treatment daily, until voluntary power begins to return. Gentle massage, especially vibratory massage, of the paralyzed muscles, should also be practised every day. Under this régime most cases of "rheumatic" facial palsy gradually recover more or less completely.

But there remains a certain proportion of cases which, in spite of massage and electrical treatment, show no signs of recovery. These are chiefly cases secondary to otitis media, or traumatic cases following operation, injuries, or fractures of the base of the skull. Until recently such cases were regarded as incurable; but within the past few years a number have been recorded in which the operation of nerve-anastomosis has yielded encouraging results.

I have elsewhere, in conjunction with Messrs. C. A. and H. A. Ballance, and also with Mr. G. L. Cheate, recorded cases where the following procedure was carried out:—

The facial and hypoglossal nerves are exposed, the facial nerve is cut across as high as possible, close to the stylomastoid foramen, and its distal segment is turned down and united by sutures to the hypoglossal, either to its side (end-to-side) or the hypoglossal is divided and its central segment united (end-to-end) to the distal segment of the paralyzed facial. The result of this procedure is

that within a few weeks the facial nerve begins to regain voluntary motor power. At first this is only manifested when the patient tries to move his tongue, but later the patient learns to perform dissociated facial movements independent of the tongue; and finally even emotional movements, such as smiling, can be accomplished by the face through the new channel of the hypoglossal. The corresponding half of the tongue, of course, undergoes atrophy, but this causes the patient no appreciable inconvenience. The original cases by Mr. Ballance and myself were done by facio-accessory anastomosis, but later results, where the hypoglossal was selected instead of the spinal accessory, have convinced us that facio-hypoglossal anastomosis is the better operation of the two.

There remains a further question: In what cases are we justified in recommending treatment by nerve-anastomosis? In other words, how long are we to wait before regarding a case as incurable without operation? I believe a good rule is to persevere faithfully with electrical treatment and massage for at least six months. If after that period no signs of return of voluntary motor power have appeared, we should recommend operation. Of course, in cases where, from traumatism, one knows that the nerve has been definitely cut across, and where it is impossible to join the upper and lower segments by primary suture, one should not wait, but should perform facio-hypoglossal anastomosis without further delay. (See also *ELECTROTHERAPEUTICS*, and *NERVES, PERIPHERAL*.)

Purves Stewart.

FACIAL SPASM (Facial Tic or Histrionic Spasm).—This disfiguring malady consists of clonic spasm of the facial muscles, and may be confined to a muscle supplied by one branch of the facial nerve or to one group of muscles, or may involve the whole of those of the affected side of the face. It is due to central causes, but perhaps also to irritation of branches of the fifth nerve.

General tonic treatment, massage, nerve tonics, and sedatives have usually been tried before the patient is brought to the care of the surgeon. Careful treatment by graduated exercises should be instituted (see *Tics*). Failing relief from these procedures faithfully carried out, 2 c.c. of 80 per cent alcohol should be injected into and around the facial nerve at its exit from the stylo-mastoid foramen. This will produce a temporary paralysis of the muscles supplied by the nerve. If this also fails to cure the condition, division of the nerve at the stylo-mastoid foramen, followed by anastomosis to the hypoglossal, is the only treatment which holds out hope of success.

James Sherren.

FAVUS.—It is a very easy matter to lay down the principles of treatment for this disease, for they are summed up in two words—epilation and antiseptics. Until recently, however, practice lagged long behind principle, and the cure of a wide-spread case of favus was rare. The barbarous pitch-cap of the Middle Ages was replaced by more humane but less efficacious methods, and it was not until the value of the *x* rays as a depilatory began to be recognized and taken advantage of, that one undertook with any confidence the treatment of favus. With their assistance one may hope to cure the most extensive case in not more than six months. The only essential is that the application be sufficient without being overdone. The method of affection of the hair makes epilation more thorough and much easier than in ringworm, and in a month the scalp should be absolutely bald. During this month, and even more after it, energetic local antiseptic treatment should be employed, so that the fragments of fungus still lurking in the empty and now open follicles may be destroyed before the new hair, which very soon begins to grow, becomes affected. Resorcin is strongly recommended by many, while various copper salts, such as the oleate and the

sulphate, and white precipitate and other mercurial ointments, also have their advocates. The following prescriptions are suitable :—

R Cupri Sulphatis	3j	Adipis Benzoati	3ij
R Resorcini	3j	Lanolini	
		Vaselini	aa 3j

Sig. To be well rubbed into the whole scalp twice a day.

Whichever be selected, the essential condition for success is that it be thoroughly massaged into the scalp, and thus into the empty follicles. *Norman Walker.*

FEVERS, ACUTE INFECTIOUS (General Treatment).—To avoid repetition it is proposed to deal in this section with such matters of treatment as are common to all the acute infections.

The patient who presents symptoms of one of these diseases should at once be confined in a room by himself, and if necessary ordered to bed. It is hardly possible to insist too strongly upon these measures, in the interests not only of the patient, but of those around him. When the symptoms are inconclusive, a few days will, in the majority of cases, determine the nature of the illness and the necessity for further isolation.

The room should be airy, with free ventilation and ample windows, and have preferably a southern aspect. If it is situated on the ground floor or provided with a balcony, so much the better, for in fine weather the patient can be wheeled or carried into the open air long before he is able to get up and walk. The upper sash of the window should be kept constantly more or less open, according to the state of the weather, care being taken so to place the bed that the patient does not feel a draught. The temperature of the room should not, if possible, be below 55° or above 65° F., but should be equable. Even in warm weather a small fire will be required, not only for heating food or drink, but for burning articles that have been used in the treatment, especially in cases of diphtheria, scarlet fever, chicken-pox, and erysipelas.

Before the patient is moved into the room, all valuable and unnecessary articles of furniture or ornament should be taken out, to avoid the risk of damage afterwards by disinfection. In these days of cheapness a small expenditure will make a room look cheerful with objects that can be destroyed when they are no longer required. Plants and cut flowers may be allowed, but the latter should be removed at night and renewed daily.

If circumstances permit, two rooms should be allotted to the patient, to be occupied and thoroughly aired alternately day and night. In diphtheria and typhoid fever, however, it is usually undesirable to move the patient more than is absolutely necessary, and one room must suffice.

During the febrile stage the patient requires but slight bed-covering—a single sheet, or a sheet and light counterpane. When convalescence is reached, blankets may be added. For children, and for adults when there is a risk of soiling the bed, as in delirium or coma, a mackintosh sheet should be placed beneath that on which the patient lies. In prolonged cases of fever, a draw-sheet and mackintosh draw-sheet should also be used. The nurse should be particularly enjoined to be careful that there are no creases in the sheets beneath the patient.

In typhoid and other prolonged fever cases in adults, it is very convenient to use nightgowns that can be opened front and back, or better still at each side. This arrangement facilitates the daily washing by the nurse and examination by the medical attendant. During the period of fever a single linen garment only is necessary.

Those in actual attendance upon the patient should not mix with other members of the household or with the outside world without taking precautions against the spread of infection, by wearing a washable outer garment or overall

in the sick-room, and by thoroughly cleansing the hands on leaving it. To hang outside the door a sheet soaked in some disinfectant is not necessary, but is useful as a warning to unauthorized visitors. Visitors to the patient must take the same precautions to prevent the spread of infection as those in attendance upon him. Dirty clothing and bed-linen should be placed in a metal receptacle and removed for disinfection by the sanitary authority every day. Soiled linen should, if possible, be steeped in antiseptic liquid before removal; this is especially desirable in typhoid fever.

At the end of the illness the room and its contents must undergo thorough disinfection, which is best carried out by the sanitary authority under the direction of the Medical Officer of Health. The floor and woodwork should be scrubbed, first with soap and water, and afterwards with some disinfectant. The walls should be submitted to the same process, unless they have been covered with paper that washing will destroy, in which case they must be re-papered. The ceiling must be re-whitened. Bedding, clothing, carpets, and books must be submitted to the heat of steam under pressure. Articles made of leather, skin, or fur are ruined by this form of heat; for them dry heat will in most instances be sufficient. Metal and wooden articles must be washed with a disinfecting solution. The nurse should be directed to mix some strong liquid disinfectant with the excreta before throwing them into the drain.

One of the results of fever (save in attacks of very short duration), is wasting, often rapid and considerable. First the reserve fat is lost, later the protein of the tissues.* One of the causes of wasting is the continued low diet to which it has been the fashion to restrict fever patients. It has been shown by Shaffer and Coleman that the waste of protein can be minimized by increasing the proportion of hydrocarbons and carbohydrates in the food. It is, therefore, not advisable to keep a patient for too long a time on purely a milk diet. While milk (2 pints) should form the staple, eggs, cream, butter, bread, cereals, sugar (especially lactose), and potatoes, should be added. The object should be to provide a diet which shall be the equivalent of 3000 to 4000, or more, calories a day. Monotony may be avoided by flavouring the milk with tea, coffee, cocoa, or chocolate; or a cup of these beverages may be given two or three times a day. Custard, junket, and milk jelly are agreeable variations. There are, however, cases in which for special reasons the diet must be restricted for a time to milk. When there is frequent vomiting, or curds are passed in the stools,† the milk alone should be given, and it should be peptonized. In very severe cases it may be necessary to limit the diet to whey or albumin water. A few persons loathe milk, and cannot take it. For them a milk-free diet, of which gelatin is one of the chief constituents, may be ordered. The gelatin should be dissolved in water, $1\frac{1}{2}$ oz. to a quart, and flavoured with lemon, etc.

Thirst is a very common complaint in fever, and there is no objection to letting the patient drink as much water as he likes. The juice of two lemons should be taken with the water daily. In severe cases of fever it is rare to find the patient hungry, so that it is unnecessary to consider the question of giving solid food till the stage of convalescence is approached. The patient's appetite is then the best guide, and by short stages the usual diet of health is soon reached. When the attack is mild, there is no objection to a fish diet (fish,‡ bread and butter, potato, rice pudding, etc.) during the earliest period.

Beef-tea, gravy, and meat soups are undesirable during the febrile stage, except as a change, and then only in small quantities and not concentrated. The extractives they contain throw too much work on the kidneys.

* The fat reserves and the body protein are lost simultaneously.—AMERICAN EDITOR.

† The American Editor believes that milk should be reduced to a minimum in such cases or eliminated from the diet.

‡ The addition of fish to the diet has not yet been justified by experimental investigation.—AMERICAN EDITOR.

In serious cases of fever, stimulation of the heart will almost certainly be required sooner or later; and the answer to the question, What is the best stimulant? largely depends upon the disease and the patient. In adults suffering from typhoid or typhus fever, for instance, the application of cold water to the skin is an excellent stimulant; but in children this measure should be used with caution. The cause of the cardiac failure in toxic diphtheria is fatty degeneration of the heart-muscle, often extreme; and in many cases stimulants are absolutely useless, because there are not enough healthy muscle-fibres left to respond. But, subject to some observations to be made below as to the use of cold water, the writer is of the opinion that the most valuable cardiac stimulants are strychnine, quinine, and wines and spirits. Camphor, also, is by no means to be despised. If, in a prolonged case of fever, the medical attendant finds signs of slowly increasing failure of the heart, he will prescribe liquor strychninæ (1 per cent), 3-5 min., or sulphate of quinine, 1-3 gr., or spirits of camphor, 5-10 min., every three or four hours. The disagreeable taste of the camphor may be disguised in port wine. Brandy, up to 4 oz. in the twenty-four hours, is also useful. With these drugs tincture of digitalis or strophanthus, or citrated caffeine may be prescribed with advantage. In desperate cases, good champagne (3 or 4 oz. every two or three hours) is preferable to brandy. But when cardiac failure comes on suddenly, the best stimulant is strychnine hypodermically, in doses of $\frac{1}{60}$ gr. to $\frac{1}{15}$ gr. of the hydrochloride. Hot coffee, with brandy, should be injected into the rectum. Hot applications to the precordial region, and flapping this region with a corner of a wet towel, are also efficacious measures at times. It is not necessary to give alcoholic beverages in a routine way; but if the patient has been accustomed to take wine, spirits, or beer, he may be allowed to have them in moderation during his illness, especially during the convalescent stage.

It is sound treatment at the beginning of an attack of fever, even though at the time the symptoms are doubtful, to give a purge; castor oil and calomel (up to 5 gr.) are the most suitable.

An abnormally high temperature frequently requires treatment. Before discussing the various methods which may be employed, it may be well to point out that a rise of temperature is not the only sign of fever, and that there is wide variation in the symptoms accompanying a rise of temperature. For a reason which has never appeared very clear to the writer, 102.5° F. has been fixed as the limit below which it is usually not needful to have recourse to antipyretic remedies. But in some patients restlessness and delirium are as troublesome with a temperature of 101°-102° as they are in others with a temperature of 103°-104°; and the writer believes that in diseases like typhoid and typhus fevers, in which the temperature is raised for many days together, the best results are not obtained by waiting till the temperature rises to 102.5° before employing such measures as baths, packs, and the like. The application of cold water to the skin in cases of fever was in use long before the invention of the clinical thermometer. When, therefore, sleeplessness, restlessness, delirium, dryness of the mouth and tongue, sordes on the gums and teeth, and a dry skin, are present, one or other of the following methods of hydrotherapy will certainly be beneficial.*

Sponging.—The patient being loosely wrapped in a blanket, his trunk and limbs should be successively exposed and sponged for about five minutes each, with a sponge partly wrung out of water. He should be left another half hour in the blanket before being put between the sheets.

Wet Pack.—The patient's trunk and limbs are enveloped in a sheet wrung out of water. He is then laid on the bed between blankets. At the end of the time

* The American Editor believes that hydrotherapy is unnecessary in typhoid fever, even in the presence of hyperpyrexia, provided the patient takes sufficient food.

specified, usually fifteen to thirty minutes, the sheet is taken off, the skin quickly and lightly dried with a towel, and the patient placed between warm blankets.

In the continuous wet pack, the patient's trunk and limbs, only so far as elbows and knees, are wrapped in a sheet wrung out of tepid or warm water. The extremities of the limbs should be wrapped in wool. The patient may be kept in the pack between blankets for several hours or days. The sheet, when it becomes dry, and if it is undesirable to move the patient in order to apply a fresh sheet, may be made wet again by squeezing water on it from a sponge. When it is soiled it must be changed.

Baths.—The patient is immersed, in the recumbent position, up to his neck in water. In this he is kept for five to twenty minutes. The baths should be repeated every three or four hours. It must be admitted that in a private house it is not always easy to give a bath to a patient who is very ill with fever, especially with typhoid fever. It is seldom that the bath available is sufficiently large. But it can be managed if pillows or pads are placed along the bottom and sides of the bath, and the patient is lowered into it with a sheet. To accomplish this safely in the case of an adult of average weight, three persons will be required. But the apparatus devised by Dr. Bull, of Auckland, New Zealand, a description of which follows, may be used (*Fig. 29*). "A piece of mackintosh sheeting, 8 feet by 4 feet, is taken; the sides are looped to receive stretcher poles; the latter should be at least 8 feet long, and 1½ inches in diameter.

Fig. 29.—Dr. Bull's Bath Apparatus.

In order to apply the bath . . . the patient is gently semi-rotated so that he lies, say, on his left side and near the edge of the bed; the mackintosh sheeting, half rolled up, is introduced under him in the same way as a draw-sheet; he is now moved again on to his back, and thus lies in the centre of the sheeting. The stretcher poles are now run through the looped sides of the sheeting, and secured to the ends of the bed, if rounded, by a simple sling; if square, they rest on them. If the head and foot of the bed are not raised, a simple support of wood for the stretcher poles to rest on is all that is necessary. A pillow is now introduced under the patient's head, beneath the mackintosh, and the sheeting at the foot is secured by a safety-pin. The bath is now ready, and water of the required temperature can be introduced, in sufficient quantity, if necessary, to cover the patient's body entirely. When the bath is over, one of the stretcher poles is drawn out, and the water allowed to flow into a receptacle at the side of the bed; this it does very readily if the bed be slightly tilted. The second stretcher pole is now drawn out, and the mackintosh sheeting removed in the reverse way to that in which it was placed beneath the patient.

This apparatus can be made cheaply and quickly. It can be applied easily by two persons, and even by one.

In hospital practice a tank on wheels is very convenient for carrying out the

bath treatment. The tank, 6 ft. 4 in. long, 1 ft. 8 in. wide, and 1½ ft. deep (inside measurements), is made of wood lined with zinc. It is supported on an iron frame, beneath which are four small, rubber-tired wheels; the two wheels at one end move on a pivot, so that by means of a handle at that end the tank is easily moved in any direction. In the bottom of the tank is a hole (with a plug) leading to a pipe, and the hole and the pipe should be large, to allow the tank to be emptied rapidly. A stretcher must be provided of such a size as can be placed easily within the tank. It should consist of an oak or teak frame on which is stretched a piece of stout waterproof canvas with a few openings cut in it, so that the water can run quickly through when the patient is lifted from the tank. A head-rest of iron rod and canvas is fixed to one end of the stretcher. A stout piece of plank about a foot longer than the width of the tank is also required. The patient, covered with a single sheet, having been moved gently to one side of the bed, the stretcher is laid upon the other. It is then very easy to shift the patient on to the stretcher with very little movement. The stout piece of plank is laid across one end of the tank. The stretcher is lifted, and placed with one extremity resting on the free end of the tank, and the other on the piece of plank. The patient's face, neck, and shoulders are then sponged for a few minutes with the water in the tank, into which, after the plank has been removed, he is gently let down. On removing him from the bath, the stretcher is placed for three or four minutes on the end of the tank and on the plank, to allow the water to run off and a dry sheet to be substituted for the wet one; meanwhile the patient's face and hair are lightly rubbed dry with a towel. He is then, without the trunk and limbs having been dried, put to bed between warm blankets—the bath-sheet being removed—with a hot water-bottle to his feet, and allowed to remain half an hour or so before the bed is properly made.

The temperature of the water used in sponging, packing, or bathing depends upon the circumstances of the case. In warm summer weather patients will enjoy a bath at a temperature of 80° F.; yet they will object most strongly to the same bath in the winter time, even though the temperature of the ward is 60° to 65° F. Cold baths are not borne well by children, old persons, and those with feeble circulation, acute or chronic. For such patients tepid or warm baths should be employed. For sponging, water at 65° to 70° should be used; but in severe cases, colder, and even iced, water may be necessary. For cold packs the water should be 75° to 80°; but in the continuous pack it should be 90° to 98°. In the strict Brand's bath-treatment the temperature of the water is 65° to 70°. But in the writer's opinion this is unnecessarily low, and he prefers a temperature of 80° to 90°, except in cases of hyperpyrexia, when iced water may be essential for baths or packs. If water at a temperature of below 80° is used, it is advisable to give the patient a stimulant just before the bath, and to administer vigorous friction to the extremities while he is in it in order to keep up a free circulation. If a bath at a lower temperature than 65° is to be given, it is best to lower the temperature from about 70° by putting in ice while the patient is in the bath. In the *continuous bath* the patient is continually immersed for a period of several days or even weeks. The temperature of the water must be 90° to 98° F. In order to carry out this form of bath in a manner agreeable to the patient and those nursing him, there must be arrangements for maintaining the water always at the same temperature, and for letting water dirtied by excreta rapidly out of the bath through a large funnel placed beneath an opening in the bed-ticking on which the patient rests. This opening is opposite the buttocks, between which and the ticking should be placed a ring-shaped air-cushion. The patient's body is wrapped in a blanket, and the tank should be covered with blankets except at the patient's head.

Cold and even tepid water, applied to the skin, acts as a cardiac stimulant.

In cases where this stimulant is not required, warm baths at about 104° F. are decidedly beneficial. Whenever the use of water is prolonged, careful observation should be kept for collapse, which not infrequently occurs.

Cold may also be applied to the skin by means of a Leiter's coil made of aluminium, placed upon the abdomen, chest, or head. A continuous stream of water at the requisite temperature is allowed to run through the coil. Or ice may be applied to the abdomen; it should be broken up into small fragments and laid upon a layer of lint, the ends of which are wrapped lightly round absorbent wool at the sides of the abdomen, so that the water from the melting ice may not run into the bed. An ice poultice is also an excellent method of applying ice. A layer of linseed meal is spread upon a piece of jaconet (or oiled silk or cambric), the edges of which have been folded over for about 1½ in. and fastened with safety-pins at the corners, to prevent the constituents of the poultice from escaping. Upon the meal a layer of ice, which has been broken up into small fragments, is laid. A little common salt should be mixed with the ice. Another layer of meal is placed over the ice. Each of the three layers should be about a quarter of an inch thick. Another piece of jaconet covers the outer layer of meal, and should be fastened at its edges to the inner piece. Between the poultice and the patient's skin a piece of lint should be applied. Lastly, the air round the patient may be cooled by suspending above him, from a cradle, a tray containing ice. The ice must be frequently renewed, and there must be a drain for the water from the melting ice.

The writer is of opinion that the methods described above are more suitable for the reduction of temperature and the alleviation of other symptoms of fever than are drugs, and that of these methods, baths and wet packs are the best. But in cases where drugs must be used in preference to these measures, quinine in 3 to 10-gr. doses, antipyrin up to 10 gr., and acetanilide (antifebrin) 2½ to 5 gr., may be given, being repeated at intervals of four hours when necessary; acetanilide is the safer of the last two drugs.

In cases of delirium, where the hydrotherapeutic methods just described are contra-indicated or have proved unavailing, restraint may have to be applied: padded side-boards, or a sheet passing over the patient's body, may be fastened to the sides of the bed. In such active delirium as occurs in small-pox and typhus fever, an attendant must be constantly at the bedside. Opium, chloral hydrate, potassium bromide, chloral formamide, sulphonal, and trional are all useful drugs in cases where other measures fail.

Headache may be relieved by the application of cold compresses, a Leiter's coil, or an evaporating lotion, with a dose of potassium bromide or antipyrin.

It is most important to keep the mouth moist and clean. This may be effected by frequently washing or swabbing it out with lemon-juice and water, or the following solution:—

℞ Glycerini Boracis (B.P.)	℥j	Aquæ	q.s. ad ℥xij
Tincturæ Myrrhæ	℥ij		

or,

℞ Liquoris Potassii	1 part	Aquæ	80 parts, or more
Acidi Carbolici Puri	1 part		

or the compound alkaline lotion mentioned in the article on DIPHTHERIA.

In all cases of continued fever, bedsores are likely to form, often with rapidity. To prevent their occurrence, the patient must not be allowed to remain too long in one position, and the skin of the back and of bony prominences must be rubbed three times a day, or whenever the sheets are soiled, with equal parts of methylated spirit and water, and dusted with starch and zinc powder. A water-bed or water-pillows are also most useful.

Retention of urine is not uncommon in cases of continued fever ; hence daily examination should be made of the bladder, and, if necessary, a catheter passed.

The nurses in attendance should be warned to look out for special symptoms, according to the nature of the disease. During convalescence, sunshine and fresh air are the best medicines, and in fine weather the patient should be wheeled or carried into the open air as soon as he is strong enough to bear the removal. As anæmia often results from a severe attack of an infectious disease, iron is frequently indicated.

A case of infectious disease having occurred in a family or institution and having been promptly removed, the question may be asked, When can it be said that no fresh cases will arise ? The answer depends upon the nature of the disease and the thoroughness with which disinfection after the removal of the first case has been carried out. Suppose a case of measles, for example, has occurred in a school ; none of the scholars who have not had the disease before can be considered safe till the longest incubation period of measles has passed, that is, three weeks. No new scholars should be admitted to the school, nor should those exposed to the first infection be sent home (in the case of a boarding-school) till three weeks have elapsed. The longest incubation period of an infectious disease may be called the " quarantine period," and will be found mentioned in connection with each disease. The necessity for enforcing a quarantine will vary according to circumstances. In some diseases (e.g., typhoid fever), it will rarely be necessary. (See ANTHRAX, CHICKEN-POX, DIPHTHERIA, GLANDERS, INFLUENZA, MEASLES, MENINGITIS, MUMPS, SCARLET FEVER, SMALL-POX, TYPHOID, TYPHUS.)

E. W. Goodall.

FIBROIDS OF UTERUS.—Treatment may be general or operative. The most common symptom caused by the fibroids is menorrhagia. The periods are unduly profuse and last unduly long. In other cases pain or pressure symptoms may be complained of, with or without menorrhagia.

The general treatment of fibroids is especially directed to shortening the duration and lessening the amount of the menstrual flow. For this purpose the patient should be advised to adopt a simple, non-stimulating diet. Meat should be taken only once a day, and all alcohol be forbidden. The bowels should be carefully regulated, and the patient recommended to lie in bed during the first two or three days of the period. Fluid extract of ergot in $\frac{1}{2}$ -dr. doses, or ergotin in 2-dr. doses, should be administered three times a day for six or eight weeks. After this time the ergot should be omitted for a week after each period has stopped, during which some preparation of iron should be substituted for it. If the excessive flow is held in check by this treatment, the patient may continue taking ergot with an interval of a week in every month, as above described, for an indefinite period, especially if she be near the menopause and the fibroids are not of great size and are not causing any other symptom than menorrhagia.

The indications for operative treatment are (1) Severe menorrhagia, unrelieved by general treatment ; (2) Severe pain, or pressure symptoms ; (3) Great size, or evidence of rapid growth.

The younger the patient the more reason is there to operate, as in such cases, the symptoms will probably become unendurable long before the menopause. The best operation is abdominal hysterectomy, partial or complete. In partial or sub-total abdominal hysterectomy, the body of the uterus with the fibroids is removed, but the cervix is left ; in complete or total hysterectomy, the body and cervix are both removed. One or both ovaries should be left.

In rare cases it is possible to enucleate a fibroid, if it is submucous, through the previously dilated cervix.

FIBROSITIS.—(See RHEUMATISM, CHRONIC.)

FILARIASIS.—The only important series of diseases in this class are those due to lymphatic obstruction caused by *Filaria bancrofti*. In the case of patients in tropical countries who harbour the parasite, whether there be any symptoms or not, it is of the utmost importance, by the careful use of mosquito nets, to prevent the possibility of the patient's re-infecting himself by the mosquitoes which have fed on him ten or more days previously. No drugs have any effect on the worm, once it is introduced into the body. For the effects of lymphatic obstruction, elephantiasis, etc., something can be done by careful bandaging and massage, especially if combined with the use of fibrolysin. As a rule, surgical operations are necessary if the removal of the deformity be desired. In the course of prolonged treatment of trypanosomiasis with atoxyl, soamin, etc., filarial embryos have been observed to disappear from the blood, but the attempts to treat filariasis by these drugs have failed, and after an interval the embryos will be found in the blood again.

Every care as regards cleanliness, and avoidance of injury and exposure, should be taken, as the vitality of elephantoid masses is low, and lymphangitis, ulceration, and suppuration readily occur. Cooling lotions, such as lead and opium wash (N.F.), and perfect rest, usually readily relieve the spurious erysipelatoid attacks that are so common in the disease.

In chyluria and hæmatochyluria, improvement rapidly results from rest, free purgation, and bland diuretics, such as boracic acid solution or alkaline carbonates, citrates, etc.

FINGER, TRIGGER.—(See TRIGGER FINGER.)

FISTULA IN ANO.—(See ABSCESS, ISCHIORECTAL; ANUS, SURGICAL DISEASES OF.)

FISTULA, BILIARY.—(See BILIARY FISTULA.)

FLAT-FOOT, WEAK FOOT, EVERTED FOOT.—Of these three terms the last is most accurately descriptive of this deformity, which essentially consists in eversion and abduction of the front part of the foot at the midtarsal joint.

The condition is produced by a disproportion between the weight to be carried and the strength of the muscles and ligaments which maintain the arch of the foot, together with erroneous deflection of the body weight too much to the inner side of the foot. Pointed boots cause abduction of the great toe and narrowing of the anterior part of the base of support of the foot; tight boots cramp the foot, and lead to disuse-atrophy of its small muscles. Rapid increase in weight, unaccustomed weight-carrying, prolonged standing, or an illness such as influenza, which depresses the muscular tone of the body, may precipitate yielding of the arch. Knock-knee causes the body weight to fall too much on the inner side of the foot, and throws an undue strain on the structures which maintain the inner half of the arch. Finally, an accident, such as a sprained ankle, may be followed by flat-foot, if care be not taken to prevent the injured foot from improper deviation of the body weight.

No treatment is fundamentally sound which does not aim at restoring the strength of weak muscles and ligaments on the inner side of the foot, first by relieving them of undue strain, and secondly by well arranged exercise. The former is attained by making the patient wear properly shaped boots, straight on the inside, so that the great toe and fore part of the foot are not abducted, and with the inner side of the heel a quarter of an inch higher than the outer, so as

to throw the body weight off the inner part of the arch on to the outer side of the foot. This alteration in the heel also makes the patient walk with his feet parallel instead of turned out. The sole of the boot must be flat and stiff, and the heel broad, or this device will not act properly.

The tibial muscles and the instep should be massaged to improve the nutrition of the weakened structures. The patient should first practise flexion and extension of the toes, and circumduction movements of the foot, in order to strengthen its small muscles; then he should proceed to tip-toe exercises, and should practise walking on the outside edge of his foot, and never with the toes out-turned.

Clinically, three types of flat-foot may be recognized :—

1. *Painful or weak foot*, which is too often diagnosed as rheumatism. This is the early stage, in which the ligaments are becoming stretched and strained. The surgeon confirms his diagnosis by eliciting pain by pressing on the spring ligament under the tubercle of the scaphoid, and also by everting the fore part of the foot. At this stage the treatment described above suffices.

2. *Painless flat-foot*. In this stage the arch has already descended, but the ligaments and bones have adjusted themselves to the new conditions. The foot is stiff and devoid of spring, the gait heavy and clumsy.

If treatment be demanded, an anæsthetic should be administered and the foot wrenched with a Thomas's wrench till it is perfectly supple. It is then fully inverted, and put up in plaster-of-Paris for two or three days. After this a thorough course of massage and exercise will greatly improve, or even completely restore, the arch and spring of the foot, provided the patient wears the boots altered as described above; if he does not, a relapse is almost certain.

3. *Painful flat-foot* is an acute condition in which the ligaments have stretched and the arch has sunk rapidly; the whole foot is acutely tender. Such a case must first rest in bed for a few days, with light massage, till the acute tenderness has passed off. The foot is then inverted and put up in plaster, after which the treatment is that described for the previous condition.

The use of plates or arches inside the boot to support the arch of the foot is fundamentally wrong, for the small muscles in the hollow of the foot are thus compressed between the plate below and the bones of the tarsus above, and cannot recover their normal function.

The treatment in each variety, therefore, when symmetry has been restored, is directed to deviate body weight from the inside to the outside of the tarsus, and to strengthen the tibial and plantar groups of muscles by exercise.

Robert Jones.

FLATULENCE.—Flatulence may be divided, according to its seat, into gastric and intestinal.

Gastric Flatulence is recognized by being associated with gaseous eructations by which it is dispelled. The commonest cause of flatulent distention of the stomach is swallowing air with imperfectly masticated food, so that it is often met with in patients who have lost their teeth, who are supplied with inefficient artificial ones, or who eat their food too quickly. It is also probable that atony of the œsophagus and of the cardiac sphincter favours the entrance of air with the food, flatulence being commonly complained of by neurasthenic patients with atonic conditions (myasthenia) of the digestive organs. Gas formed from fermentation rarely occurs in the stomach, because the food does not remain there sufficiently long for such processes to take place; but where there is pyloric obstruction with food stasis, fermentations, with the production of carbonic acid, sulphuretted hydrogen, and marsh gas, may take place.

The rational treatment of stomach flatulence is not the use of anti-fermentative

drugs, but of means to secure that the food is well masticated before being swallowed. Meals should be as dry as possible. Where flatulence is present, it may be got rid of by the use of remedies, such as ginger and other so-called carminatives, which stimulate the stomach peristalsis to expel the gas through the mouth or downwards into the bowel. The much-lauded creosote perles probably act, not by any anti-fermentative action, but by the irritating effect of the carbolic acid contained in them on the mucous lining of the stomach. Where there is stasis from pyloric obstruction, the proper treatment is gastro-enterostomy or the use of the stomach tube (lavage). (See also ERUCTION, NERVOUS.)

Intestinal Flatulence is caused to some extent by the passage into the intestine of swallowed air, but is more commonly than stomach flatulence the direct result of the fermentation of cellulose, forming carbonic acid gas and sulphuretted hydrogen. It can be recognized by the absence of eructation and the localization of the tympanites in the bowels, which can be determined by abdominal examination. The main condition that favours intestinal fermentation is fæcal stasis, so that constipation must be looked upon as the real cause to which treatment should be directed. It is desirable to exclude from the diet vegetables containing much cellulose, such as cabbage, especially where the constipation is of the spasmodic type.

Successful treatment depends on overcoming constipation rather than on preventing fermentation, especially as articles of food containing cellulose, which ferments, are those which favour peristalsis. In that form of constipation which is associated with spasmodic contraction of the colon, it is necessary to avoid giving stimulating food, and we must endeavour to overcome the spasm by the use of sedatives. Enemata of warm olive oil ($\frac{1}{2}$ -pint) are perhaps the best means of dealing with constipation due to spasm. Belladonna is invariably recommended because of its physiological effect, but is disappointing; still the menthol and belladonna pill may be tried. (See also CONSTIPATION.)

Robert Saundby.

FOREIGN BODIES IN THE AIR-PASSAGES OR ŒSOPHAGUS.—The history of pain after swallowing a foreign body frequently connotes a mere abrasion of the mucous membrane. This fact is so well known and generally recognized that it may become a source of danger to the patient, obscuring, as it often has done, a genuine diagnosis of the condition; for the detection of such a wound does not of necessity negative the presence of an impacted foreign body in some other situation. If the severity and the situation of the wound fully explain the symptoms complained of, the lesion may be treated by the frequent application of hydrogen peroxide (half a teaspoonful at 3-vol. strength may be sipped at hourly intervals), while frequently one or two topical applications of solution of nitrate of silver (1 dr. to 1 oz.) will dispel the symptoms and clinch the diagnosis. Strong silver solutions are very irritating to the larynx, and the small swab employed for their application should be shaken dry, lest a drop should fall into that organ.

Experience shows that the ability of the patient to localize the position of a wound or foreign body in the throat is very imperfect, and affords no safe guide. In lesions of the tonsil the patient frequently refers his symptoms to the level of the larynx. The case is well known of an experienced laryngologist who for many days affirmed that a foreign body was lodged in his own pyriform fossa: it was ultimately found, however, in his postnasal space. The power of localization at the base of the tongue and in the valeculæ is fairly accurate. The examination of the valeculæ with the mirror is often difficult without

special appliances, and a sweep of the finger first on one side and then on the other of the frenum of the epiglottis will, as a rule, do all that is required both for diagnosis and treatment in this region.

The tonsil is the most frequent seat of impaction of a small, sharp, foreign body such as a pin or fishbone. Here palpation is often delusive, and a careful examination under powerful illumination is necessary. Unless the patient is docile and the illumination adequate, mistakes may easily be made, and it is advisable to apply a local anæsthetic before manipulating with probes and forceps. This is best done by inserting a swab of cotton-wool half the size of a pea, carried on the end of a probe and soaked with 20 per cent cocaine, into the fossa at the upper end of the tonsil (the "supratonsillar fossa" of older text-books), and leaving it *in situ* for five minutes, the patient holding the probe between his molar teeth. A small semi-transparent fish-bone is not easily detected; moreover, the minute bead of exudation often seen at the mouth of a crypt can be mistaken for the butt-end of a fish-bone, particularly if it be surrounded by a red areola.

It is of the utmost importance that the foreign body, when detected, should be seized with certainty and precision at the outset; hasty attempts at removal under imperfect illumination often result in driving the object deeply into the tissues, with the possible sequel of an elaborate search made under the much more difficult conditions which accompany general anæsthesia.

Any approach to roughness in dealing with these cases can readily lead to laceration, sepsis, and fatal mediastinitis. Furthermore, the experience of the most skilful surgeons shows that it is easy to be mistaken in these cases, and foreign bodies have been ejected or found post mortem when their presence has been denied after careful search. It is therefore important that surgeons who do not profess special skill in throat work should be extremely cautious in expressing the definite opinion that a foreign body is absent.

The general statement may be made that the presence of a foreign body in the air-passages or the upper digestive tract may always become the source of genuine danger, and that the examination must always be made with extreme care, and the treatment conducted with perfect precision. If the matter is approached in this spirit, there is no reason to-day, thanks to modern developments of technique, why any practitioner should not find himself competent to deal with such cases, granted the presence of certain instruments, a set of which should be kept at every cottage hospital.

With regard to the nature of the foreign bodies hitherto recorded, and their seats of impaction, tables may be consulted*; but as the unexpected must be looked for, the surgeon will in practice rely—(1) Upon the history given by the patient or friends; (2) Upon ocular or digital examination; (3) Upon radio-scope findings.

In the case of large bodies impacted in the pharynx, or of inflammatory swelling of that part resulting from injury, the functions of respiration and of deglutition will both be affected. The diagnosis may generally be established by the history, by direct inspection with tongue deeply depressed, and by the finger. With regard to palpation, two points must be remembered: (1) That a foreign body may be dislodged thereby, and shifted well into the larynx; (2) That dyspnoea may be increased by the addition of spastic closure of the glottis. The surgeon, therefore, should in all cases be prepared to open the windpipe.

In an emergency, both the safest, quickest, and easiest route into the windpipe is through the cricothyroid membrane. Even in infants and stout adults

* StClair Thomson, *Diseases of the Throat and Nose*, 1912; Howarth's translation of Brüning's *Direct Laryngoscopy*, etc., 1912.

the hard upper edge of the cricoid cartilage can be detected by palpation. It is felt as a well-defined, horizontal rim, quite unlike the notch above the pomum Adami. The upper edge of the cricoid being defined with the index nail of the left hand, a narrow knife-blade (and preferably a blunt one), held 'short' and horizontally between the thumb and index of the right hand, is thrust through skin and cricothyroid membrane into the subglottic space, and the wound is immediately dilated either with dressing forceps or improvised retractors: better still, fitted with an improvised tube large enough to be gripped so tightly in the cricothyroid wound as to form a watertight joint. If the knife is made to graze the upper edge of the cricoid, the small cricothyroid artery will not be wounded; while if the knife is blunt, the veins are likely to escape puncture; but should hæmorrhage occur, the patient must be turned semi-prone, and blood be wiped away at each exhalation until hæmostasis, generally spontaneous after respiration is restored, is obtained. When time permits, it is possible to avoid the danger of wounding the veins by incising the skin first, and preferably by transfixion of a fold drawn forward by the operator and an assistant. Danger of the inhalation of blood is obviated by the flattened cricothyrotomy tube of Bond, which fits tightly into the wound. Cricothyrotomy is a temporary measure, for the tube in this situation can seldom be tolerated for more than a day.

The operations of tracheotomy need not be detailed in these paragraphs (see LARYNGEAL OBSTRUCTION), but a bloodless and rapid method may be mentioned. After the skin incision, the knife is definitely laid aside till required to open the trachea. Two blunt double-hook retractors are held one in each hand, and the prongs pressed into the tissues immediately below the level of the lower edge of the cricoid cartilage, not exactly in the middle line, but transgressing it by a sixth of an inch, the two instruments overlapping. If forcible retraction is now made, no remnant of tissue can remain in the middle line to obscure the view, while the absence of cutting edges ensures a perfectly dry wound resembling that of a post-mortem operation. Three or four retractions made in this way, and at varying levels, will expose either the pretracheal fascia or the isthmus of the thyroid gland. If the isthmus needs to be severed, a horizontal snick is made with scissors immediately below the cricoid through the pretracheal fascia which attaches the isthmus to that cartilage. Through this snick two hæmostatic forceps are inserted close to the middle line, and their jaws thrust down towards the sternum and then closed, to clamp the entire width of the isthmus. If now the handles are forcibly separated so as to lie across the neck, the isthmus is thereby torn through in the middle line, and each half is ligated at leisure. The object of this manœuvre is to avoid hæmorrhage from the veins about the isthmus, and particularly from the plexus below it. The jaws of the forceps, therefore, must not transgress the lower edge of the isthmus—a matter determined by palpation, unless, of course, the details of the venous plexus are visible. It must be admitted that the chief cause of delay and difficulty in tracheotomy is hæmorrhage from these veins, resulting from the use of the knife where no knife is needed—for the operation as described above can be performed in two minutes even on an infant a few days old.

Though all cases of foreign bodies in the air-passages are in a sense urgent, they may for practical purposes be divided into two classes: (1) *Emergency cases*; and (2) *Deliberate cases*.

1. **Emergency Cases.**—These are most commonly met with in the operating theatre, and particularly when the pharyngeal and laryngeal reflexes have been abolished by deep chloroform anæsthesia. The surgeon should take many opportunities of habituating his finger to the feel of the normal larynx, for the uninitiated may at a critical moment find himself in doubt as to whether he

is touching a normal arytenoid or a fragment of impacted tonsil or turbinate; his doubts may be increased if after seizing a suspected foreign substance he finds it to be, as is sometimes the case, firmly held by the vestibule of the larynx, which can act as a prehensile organ of some power. A piece of sponge coated with blood-clot, or a piece of vomited food, sometimes proves an object difficult to detect with certainty, and forcible traction must not be made upon it until its identity has been arrived at by exclusion of the epiglottis and arytenoids. It should be remembered that during spastic closure of the vestibule the arytenoids are tilted well forward: thus the finger comes down upon their posterior surface. It is better to perform cricothyrotomy than to tear out an arytenoid. Tactile skill with the finger has the additional advantage of enabling the operator to pass a blunt, flat instrument, such as the handle of a probe, through the posterior half of the glottis and, by rotating the instrument through 90°, hold the vocal cords apart. It is an obvious fact, and therefore one well to remember at non-critical moments, that artificial respiration is worse than useless when the airway is blocked.

Foreign bodies are commonly inhaled as a result of talking and laughing when the mouth is full of food, or during the involuntary inhalation which precedes a sneeze or punctuates emotions such as surprise, anger, or fear. In this way needles or tinctacks, coins and toys, bones and toothplates, sweets and beans, nuts and grassheads, as well as legitimate food and drink, are suddenly drawn into the larynx. As a rule the first contact with that organ causes sudden closure of the glottis and quick expulsion, followed by temporary spasm and aphonia; but in the unfortunate exceptions, either the vestibule in its contraction, or the cords themselves, grip the object tightly and even bury a sharp point firmly in the tissues, and the condition becomes one of urgency if the foreign body is large enough to cause genuine obstruction: for it would seem that the spasm induced by the presence of a small body does not end fatally, at all events in the adult.

The dyspnœa resulting from mere spasm may be treated in the following manner, as described by Semon. The patient must, by a mental effort, resist the natural impulse to make a deep inhalation; on the contrary, he must hold his breath while he counts ten, and then with the mouth closed he should make very shallow, rapid respirations through the nose. It is said that when the necessary presence of mind exists, this process will invariably and quickly relieve the dyspnœa, granted of course that no foreign body remains in the larynx.

When obstruction is complete, the case can only be saved on amateur first-aid lines—namely, by partial inversion of the person with violent slapping of the back, by inversion and jolting in a child, and by using the finger or by immediate opening of the windpipe.

In emergency cases brought to the doctor, some space for respiration remains. His chief guide will be the history, aided by inspection with tongue-depressor or mirror (and if possible he should allay spasm by spraying with 5 per cent cocaine before attempting examination); but in any case his first thought should be to be prepared for cricothyrotomy. No palpation should be attempted until a pocket-knife is open and ready; for displacement of the object may cause immediate and complete obstruction. When palpation reveals the presence of a dangerous body, such as a tooth-plate or bone, firmly held in the vestibule, the case should be converted from the emergency to the deliberate class by the performance of cricothyrotomy; for the hasty, forcible, and blind removal of such a body may not only cause permanent damage, but will almost certainly require to be followed by tracheotomy.

In no case should distressing dyspnœa be allowed to persist for any length of time, and the absence of cyanosis cannot be taken as a criterion of the safety of

the patient; slow asphyxiation, with ultimate sudden collapse, may be accompanied by pallor without cyanosis. In all cases of doubt, the airway should be opened or the doctor remain in attendance.

There exists a second division of emergency cases, where attacks of intense dyspnœa alternate with periods of comparatively, and indeed sometimes of complete, ease. Such a condition may be brought about by the displacement from time to time of an object not firmly fixed in the larynx, but held sufficiently tightly to withstand the expulsive efforts of coughing. These alternating attacks of dyspnœa and comparative ease are, however, typical of the presence of a body lying loose in the trachea, and thrown by the act of coughing from time to time into the subglottic space—which, needless to say, is much smaller in diameter than the trachea. Such a case must not be left by the surgeon for a moment until permanent relief is obtained. A surgeon thoroughly used to the manipulation of the bronchoscope and forceps would keep the patient perfectly at rest in one position until the arrival of instruments for removal by the peroral method; but in any case he would make all preparations for tracheotomy, and under many circumstances would freely expose the trachea before commencing peroral manipulations. In these cases tracheotomy and not cricothyrotomy is indicated, and the windpipe should be opened widely, and as low as possible. As a rule a loose body is expelled as soon as the trachea is opened; but it must always be remembered that however low the tracheotomy opening may be, the foreign body can and may remain below it, and may need removal with forceps. Possession of the bronchoscopic instruments should, as a rule, render this a simple matter; but where these are lacking, the forehead mirror and reflected light should be used. Although it will be obvious to the surgeon as soon as he has opened the trachea, it may be well here to emphasize the fact, so that he may complete his preparations, that tracheotomy *per se* does not relieve the patient from imminent danger. A change in the position of the foreign body may at any moment obstruct the tracheotomy tube and even the entire tracheal lumen, apart from the fact that it may enter a bronchus. The body, therefore, must at once be removed, and to this end advantage should be taken both of the plasticity of the trachea and of its comparative freedom in the freshly-made wound, conditions which may even allow a direct view of the bifurcation to be obtained. The patient should lie supine on the table, with his head over the end of it supported by hand, and the chin turned as far as possible to the left. The surgeon will look down the trachea over the patient's right shoulder, the hole in the forehead mirror being opposite the operator's right eye, and the source of illumination held to his right front. The light should be so placed as not to shine into and dazzle the left eye. So far as may be possible, the tracheal axis is now drawn into the operator's line of vision by means of a flat instrument such as the handle of a retractor held in the left hand or by an assistant, the mucous membrane having been desensitized by cocaine. The view will be facilitated by stitching the trachea to the skin; such stitching must be 'through and through' the tracheal wall, and must include a cartilage ring. With a trachea half filled with a foam of blood-stained mucus, an effective view may be difficult enough to obtain, and great patience may be necessary. Small pieces of loose-textured marine sponge held in forceps will be found serviceable for the removal of mucus, while cough may be allayed by painting the carina or ridge at the bifurcation with 20 per cent cocaine. In any case a proper view must be obtained, and distances well realized, before any attempt is made to extract with the forceps, otherwise the surgeon runs a risk of seizing and lacerating the carina. After a satisfactory but fruitless search below, the upper portion of the trachea should be examined, and also the pharynx, nasopharynx, nose, mouth—and even the tube, for after tracheotomy the foreign body may be

expelled through the glottis and escape unobserved. If necessary, the chest should now be examined for evidence of deficient air-entry, indicating obstruction of one or other bronchus. Foreign bodies enter the right bronchus more readily than the left, owing to the more acute angle at which the former leaves the tracheal axis (see p. 374) and to its greater size, which is nearly equal to that of the trachea: to obtain a view of it the surgeon will look over the patient's left shoulder, with the chin of the latter turned to the right.

With complete obstruction of one bronchus, and consequent absence of any expulsive power behind the foreign body, the case passes into the second category, and will be dealt with under the head of 'deliberate' cases.

2. Deliberate Cases.—The word deliberate is used merely to imply that the condition of the patient permits of an hour or so in which to make adequate preparations and to plan a course of action after complete diagnosis.

Many cases are on record where foreign bodies have been retained for months and even years without serious ill-health; but in general it should be considered that all cases are urgent, seeing that at any time dislodgement, ulceration, inflammatory swelling, and particularly septic bronchitis and pneumonia or pulmonary abscess, may supervene.

A foreign body in the larynx may be suspected from the history, subjective symptoms, alterations in the voice, and stridor. Cough may be absent, and dysphagia may be present. Diagnosis may in general be completed by laryngoscopic inspection, and in young children a view of the larynx in the mirror is often best obtained by drawing the base of the tongue forward with the hooked end of the left index finger. If this fails, one or other of the direct methods may be employed; these will be described later. Where radiography can be brought into play, both a lateral and an anteroposterior view should be taken, or the stereoscopic method employed. By these means the size, shape, and disposition of an object opaque to the rays is determined—and, in parenthesis, it may be taken as a rough rule that when an anteroposterior view shows a flat object, such as a coin, fixed in the sagittal plane, it will prove to be in the larynx; in the transverse plane, in the pharynx.

This is not the place to discuss details of radioscopy concerning the relative opacity of various materials, for advances in the technique of that branch of the art are being made daily; but anatomical considerations are important, and will be considered in the section dealing with endoscopic methods.

A foreign body in the larynx detected by means of the laryngoscopic mirror may of course be removed with laryngeal forceps if the requisite skill is available to make use of them under visual control. This article, however, is intended for those untrained in laryngology, and consideration will now be given to the direct methods, which have revolutionized the surgery of foreign bodies in the throat.

ENDOSCOPY OF THE AIR-PASSAGES AND ŒSOPHAGUS.

It is now nearly a decade since laryngologists adopted, as one of their routine and everyday methods of examination and treatment, the employment of straight spatulæ and tubes introduced into the air and food-passages. As a consequence, the surgery of many diseases, and particularly the treatment of 'foreign body' cases, has been revolutionized; and it is a source of surprise to some of us that this fact is not more generally recognized, and indeed that these methods have not become part of the ordinary manœuvres of medical practice. At one time the cost of instruments was high, but to-day a very efficient and compact set, meeting general requirements, can be purchased for a few guineas (e.g., Brünings' set, *vide* the surgical instrument catalogues, price about sixteen pounds, exclusive of an electric accumulator).

It goes without saying that extremely baffling cases will occur in this as in every other branch of surgery; but the difficulties and dangers to be expected are comparable to those which accompany the use of urethral and uterine instruments, and may be met by conscientious care, delicacy of touch, and patience. There is nothing occult about these manœuvres, and they are, in a sense, less 'technical' than those of ordinary laryngology and ophthalmology. At the least, every cottage hospital should be equipped with a set of instruments, and one member of the staff could, after a short course of attendance at any hospital throat department, learn enough to be of practical value; for the chief requirements of the endoscopist are good or well-corrected eyesight, cautious judgement, and the careful and gentle handling which all delicate surgery demands. In a word, the pioneer work in this department has been accomplished, and the regions of surgery opened up are ready for general occupation.

If asked for advice by a doctor responsible for the surgery, say, of an isolated township in the Colonies, I would make the following suggestions: (1) The purchase of Brünings' set, with the addition of two spare bulbs for the suction apparatus, six spare electric bulbs, a pair of Paterson's laryngeal forceps, and a ten-volt accumulator with a rheostat. If funds are forthcoming for a more complete armamentarium, Brünings' *Direct Laryngoscopy*, etc. (English translation by Howarth) may be consulted: but no armamentarium can be absolutely complete. (2) A little practice in using the forceps through the bronchoscope to pick up small objects, in order to accustom the eye to judging distance by monocular vision. (3) Practice upon the cadaver. This is in some respects more difficult than practice *in vivo*, but it will give some idea of the small degree of force required to overcome friction.

Care must be taken not to dent the tubes, which are made of soft metal, otherwise the inner or extension tubes will cease to run smoothly in the outer tube or spatula. Forceps and probes must not be bent in cleaning, or their shafts will obstruct the view when used in the tubes. The light must be focussed at the appropriate distance by rotating the cap which carries the condensing lens, and it should also be centred correctly by fixing a tube to the handle and adjusting the mirror. It is for this adjustment that the two small fibre-covered handles are intended. It will be noted that a slide enables the upper and lower portions of the handle to be separated by nearly three inches, in order to facilitate the use of forceps, etc., and that the upper portion can be turned to one side to enable the extension tubes to be inserted into the tube spatulæ. The spring-like handle of the extension tube will bend and kink unless held 'short' during its propulsion down the spatula. In adjusting the forceps at the length appropriate to the case before commencing operations, the jaws must be tested to see that they come firmly together.

ANATOMICAL DETAILS.

Some knowledge of anatomical detail other than that obtained in the dissecting-room is necessary, if the results of radiography are to be of value and the endoscopic manœuvres conducted with ease; what follows will serve as a useful general guide, and it is simply expressed by the accompanying diagram (*Fig. 30*), in which the measurements stand for those of the average adult male, and of a child of about six, respectively.

Certain points may especially be noted:—

1. The trachea is a much shorter organ than one is apt to imagine. From 4 to 4½ inches in the adult male, and 3½ to 4 inches in the female, are average measurements, and as a general rule the bifurcation lies at the level of the sternal articulation of the second rib. A fairly accurate gauge of the limits of any

individual trachea may be formed by marking the positions of the 6th cervical spinous process and the interspace between the 4th and 5th dorsal.

2. The right bronchus leaves the tracheal axis at a small angle (e.g., 25°), and for its first inch it is sometimes nearly as large as the trachea. Moreover the

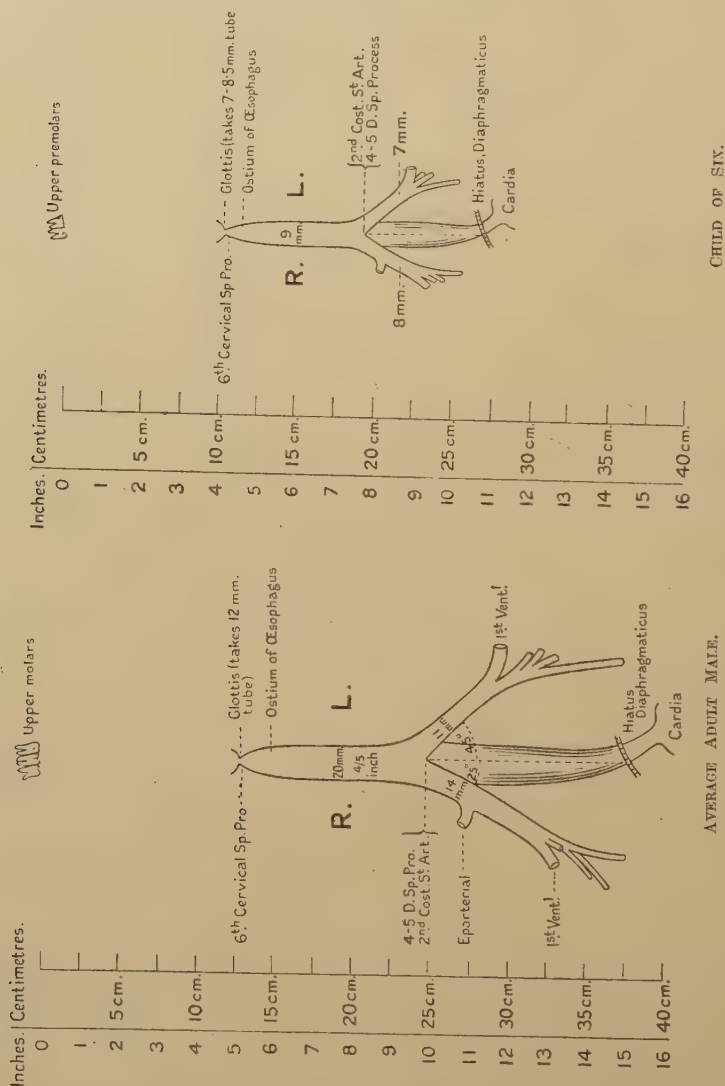

Fig. 30.—Anatomical details of air-passages and esophagus.

carina or crest between the two bronchi is placed a little to the left of the centre of the trachea, and consequently the right bronchus may, at a hurried glance, appear almost a direct continuation of the trachea. For these reasons foreign

bodies are apt to enter the right bronchus rather than the left. The ancient saying may be remembered that a shilling will enter the right but not the left bronchus. The shilling would not, however, pass down more than an inch, at which distance the eparterial bronchus is given off at a right angle. Below this point comes a narrower portion about two inches in length, at which distance division again takes place.

The left bronchus leaves the tracheal axis at a much greater angle (45° to 60°), thanks to the displacement of the left lung by the heart and to the necessity for the bronchus to sweep outwards under the arch of the aorta. As a consequence, the first view obtained of it through the tube is that of the floor of the bronchus, but as the instrument is gently pushed down it, the bronchus straightens out. For two inches it remains undivided, and then a large ventral branch is given off. In all, about eight branches are given off by each main bronchus. The position of the aorta, first in front, then to the left side, of the trachea, and finally arching to the back of the left bronchus, will be recalled.

3. As to calibre: a full-sized trachea may be nearly an inch in diameter (23 mm.), and the first inch of the right bronchus may be little short of it. (An adult male with measurements twenty-five per cent less than these figures would, however, be no abnormality.) Very large tubes, therefore, may be inserted through a tracheotomy wound ("inferior bronchoscopy"); but in the peroral method, the size of the tube is limited by the available width of the glottis, and this in an adult male may not be more than half an inch.

As the instruments are marked on the metric system, and as the reader thinks in inches, and is unwilling to do division sums during an operation (i.e., centimetres $\times \frac{2}{5}$ = inches; and millimetres $\times \frac{2}{50}$ = inches), one may remark that a 25 cm. tube is 10 inches long, and will just reach the bifurcation; and that a tube 12 mm. in diameter is about as large as will pass the glottis in a male adult. Brünings gives the available width of the glottis as follows: Man, 12 to 15 mm.; woman, 10 to 13 mm.; child, 8 to 10 mm.; infant, 5 to 6.5 mm. He has adapted his tubes accordingly. Needless to say, the larger the tube the better the view; for though the illumination is more than sufficiently brilliant with the smallest tubes, the limited area seen adds to the difficulty of recognizing the parts in view at any one time.

4. It is unnecessary to burden the memory with figures relating to various ages—it is better in each case to consider that the trachea bifurcates about the fourth or fifth spinous process, or behind the second sternocostal articulation; and in order to avoid distortion of the skiagraphic picture, and to facilitate its interpretation, the direction of the rays should be horizontal, and the points mentioned should be marked on the skin by the application of opaque objects.

5. The œsophagus commences above at the lower border of the cricoid cartilage, at which level a thick band of the fibres of the inferior constrictor pharyngis forms a definite ridge projecting from the posterior wall of the gullet. Thus a well-defined ostium or mouth of the œsophagus is formed, and it is often spoken of as the cricoid constriction. Thanks to the contiguity of the cricoid cartilage, the ostium at rest takes the form of a transverse slit; but with a little distention (e.g., during the swallowing of a large bolus of food) it readily expands to an oval orifice nearly 1 inch in lateral, and $\frac{3}{5}$ inch in anteroposterior, diameter. These figures are important to remember in view of the possible passage of large foreign bodies, but they have little reference to the choice of tubes. Though the ostium may be 17 mm. in anteroposterior diameter, it is seldom possible to pass a cylindrical tube larger than 14 mm., by reason of the pressure involved against the upper teeth. The 10 mm. tube will pass in a small child.

The hiatus diaphragmaticus is also a slit-like orifice, with its long diameter sloping obliquely from in front backwards and to the left. This orifice is also

very distensible, and has been dilated to a diameter of over 2 inches. The short diaphragmatic and abdominal sections of the œsophagus are directed to the left and forwards to enter the stomach; but the angle varies greatly with the degree of distention of the stomach, and also with the position of the patient, for the lumen is in a large measure straightened out when the patient is either sitting or in the right lateral recumbent position.

The walls of the main portion of the œsophagus are so distensible that for purposes of practice the size of the lumen need scarcely be considered. The organ as it descends through the thorax tends to sweep slightly to the left and forwards away from the spine, and in front of the aorta to make its passage through the diaphragm. This, however, is not always the case; the viscus may be practically straight, and a view may occasionally be obtained of the hiatus soon after the œsophagoscope has passed through the ostium.

6. At his first essay in œsophagoscopy the surgeon may be surprised to find that the thoracic œsophagus is, when normal and at rest, a cylindrical, hollow viscus containing air. This is not surprising when the phenomenon of aspiration of the thorax is considered. When the end of the œsophagoscope has passed about $1\frac{1}{2}$ to 2 inches beyond the ostium, a view is obtained of several inches of the hollow organ, the lumen expanding and narrowing slightly on inspiration and expiration respectively. On the left anterior wall may be seen slight bulgings due to the presence of the aorta and of the left bronchus—these are brought out prominently by artificial distention of the lumen with air. The position of the aorta, at first to the left, then to the back of the œsophagus, will be recalled by the pulsatile movements seen.

7. The length of the œsophagus varies greatly,—even in the same individual under the varying conditions of the stomach. The distance of the cardia from the teeth varies from 14 to 20 inches; but Brünings, from collation of the figures of many authorities, arrives at 16 inches as the commonest length in man, 15 in women, about 13 in the child of fifteen, and about 11 in the child of six. The distance from the teeth to the œsophageal ostium is in adult man 15 cm. (6 inches), in women 14 cm. ($5\frac{1}{2}$ inches), and in the child of six 11 cm. ($4\frac{1}{2}$ inches).

The rapid appreciation of the metric values in their English equivalents is much facilitated if it be remembered that, roughly speaking, a metre = 40 inches, a decimetre or 10 cm. = 4 inches, a centimetre = $\frac{1}{10}$ inches, and a millimetre = $\frac{1}{100}$ inches. Thus, 11 cm. = $\frac{44}{10}$ inches, and 17 mm. = $\frac{68}{100}$ inches; these are figures which readily convey an idea to the British mind.

METHODS OF EXAMINATION.

Hypopharyngoscopy.—The lower portion of the pharynx, that which remains hidden from view in the laryngoscopic picture by the apposition of the base of the arytenoids to the posterior wall, can be brought into view by von Eicken's method. After the interior of the larynx has been anæsthetized with cocaine, the laryngeal mirror is inserted in the usual way, the patient craning his neck forward from the shoulders. A strong curved probe, armed at the tip with wool or a rubber covering, is inserted between the cords, and the larynx is drawn bodily away from the spine with a firm pull. A view is thus obtained for a few seconds of the posterior surface of the cricoid and of the cavity of the hypopharynx down to the œsophageal ostium. A better view may be had, and a more prolonged examination made, by Killian's suspension method (see p. 377), coupled with retraction of the larynx from the spine. This latter manœuvre may be accomplished conveniently by tilting the cricoid forward first on one side then on the other by inserting a flat, blunt-edged instrument into the hypopharynx and rotating it upon its long axis. A careful and prolonged examination of the lower portion of the hypopharynx, such as is required for

the determination of the lower limits of a malignant growth, is best made by the ordinary direct method, a broad tube spatula being employed.

Direct Laryngoscopy.—As a rule this is accomplished in the adult under cocaine anæsthesia and in the sitting position. With a small swab wet with equal parts of cocaine (20 per cent) and adrenalin (1–1000) a sweep is made over the base of the tongue, and the posterior surface of the epiglottis is then carefully painted. A second application is made to the whole interior of the vestibule, including the vocal cords. A third application may be necessary, and in irritable subjects bromide may be given for three days, or morphia (gr. $\frac{1}{6}$) one hour before operation. The operator stands before the patient, who is seated on a low stool and leans forward at an angle of about 45° to the perpendicular. The surgeon, grasping the handle of the electroscope firmly in the left hand, gently inserts the tip of a tube spatula into the larynx, and with a rotary movement round an axis transverse to the tube (in which the upper teeth must on no account be allowed to play the part of fulcrum) he draws the epiglottis forward, the whole manœuvre being directed under visual control. In many cases the anterior half of the glottis will remain hidden from view until with his right hand the operator (or assistant) presses the anterior surface of the cricoid cartilage back towards the spine. Mosdher's or Hill's tube spatulæ, which are open at one side, facilitate the use of probes and forceps held by the operator in his right hand.

Spastic closure of the glottis is readily overcome by passing the flat handle of a probe through the glottis, and rotating it on its long axis through 90° into the transverse position. The same effect is attained by passing Paterson's forceps into the glottis and opening the blades. A small-size bronchoscopic tube may also be passed; but this completely obscures the view for the time being.

At the present time surgeons who find frequent occasion to attack the larynx by the direct method make use of Killian's suspension method. The apparatus, which is still in process of evolution, need not be described in detail here; let it suffice to say that the patient lies recumbent with his head over the edge of the table; a straight spatula suspended from a gallows supplied with screw movements for fine adjustment is inserted into the larynx, and the weight of the head serves to retract the tongue, epiglottis, etc., and prevent them from obstructing the view. By this means the operator is left with two hands free for delicate work. Some such apparatus could readily be improvised, but in practice it is found that the fine adjustments form a necessary element in the successful use of the principle of suspension laryngoscopy.

In children, thanks to the high position of the larynx, a momentary view can often be obtained by the direct method without general anæsthesia; but here, as indeed in all laryngeal manœuvres, the preparations for cricothyrotomy or tracheotomy should be complete.

It may here be mentioned that in ordinary laryngoscopy with the mirror, the base of the tongue in young children should be hooked forward, either with the finger or a spatula with a down-curved end—e.g., Lack's.

Inferior Tracheobronchoscopy.—Examination of the parts through a tracheotomy wound is a very simple matter, provided that the thyroid isthmus has been divided, that the tracheal opening is low, and that the manœuvres are carried out at the time of the tracheotomy, i.e., before the trachea has become fixed deep in the neck by adhesions. When delay is imperative, the edges of the tracheal fistula should be stitched to the skin, two or more tracheal cartilages being included in the sutures. Inferior bronchoscopy is the method of choice in dealing with very large and sharp foreign bodies, or with those likely to break up when seized in the forceps.

Peroral Tracheobronchoscopy and Oesophagoscopy.—It is impossible in a few paragraphs to give anything like a complete exposé of a subject which can readily occupy a volume ; it must suffice here to indicate the guiding principles, supplemented by a few practical hints.

Anæsthesia.—The manœuvres are not painful, but they make a heavy demand on the morale of the patient ; therefore general anæsthesia is almost essential in children, and very often required in adults where any prolonged retention of the tube is likely. In a good adult subject cocaine anæsthesia is quite sufficient, and may be preceded by a dose of morphia (gr. $\frac{1}{4}$) and atropine (gr. $\frac{1}{120}$) given an hour before operation. The latter drug is helpful in that it diminishes the secretion of mucus and saliva. The dazed condition induced by scopolamine and morphia is preferred by some surgeons. In any case, the local application of cocaine is necessary to allay purely reflex phenomena ; it must be applied carefully to the laryngeal vestibule, the carina, and the ostium of the œsophagus, and specially to the inflamed or irritated area round an impacted foreign body.

In all local anæsthetic cases the patient must be assured that the tube shall be removed directly he indicates that its presence has become intolerable—and this moral compact should never be broken. Two slaps of the hand upon the thigh serve as a useful, because natural, sign, while one slap may be employed to indicate painful pressure upon the lips or teeth, a matter easily put right by a slight adjustment.

For general anæsthesia ether must be avoided, as it induces hyperæmia and secretion, and increases the risks of pulmonary complications. In the writer's opinion chloroform is the anæsthetic of choice for these cases.

Needless to say the stomach should be empty in every case.

Posture of patient.—For the direct examination of the larynx, trachea, and hypopharynx in adults, the sitting posture is the more convenient for both surgeon and patient ; for prolonged examination of the deeper parts, the lying position is preferable, but by no means essential.

When the long tubes are to be used, the important point to bear in mind is that the upper teeth have to be brought as near as possible into line with the lumen of the trachea or œsophagus, and as a corollary, that the spine should be as straight as possible. This does not by any means imply that the back should be "straightened" as that term is generally employed ; on the contrary, the normal curvatures have to be effaced so far as possible, and the attitude of choice is that approaching the posture of a cyclist leaning over his handle-bars.

In the case of a sitting patient, he should be seated on a low stool without a back, and should bend forward from the hips at an angle of about 45° , the position being retained by a nurse standing behind him with her knee against the small of his back. The neck is craned forward somewhat from the shoulders, so as to bring the cervical into line with the now straightened dorsal spine ; while a little additional space is afforded by extension at the atlo-axial joint, the patient looking up towards the ceiling. This latter movement must, however, be but slight, otherwise curvature of the cervical spine as a whole will result.

In the lying posture which is employed in chloroform cases, the same principles are involved. The decubitus may be dorsal or right-lateral, and in either case the head is drawn over the end of the table and supported on an adjustable head-rest or by a nurse whose whole attention must be directed to this duty, often an arduous one. She should therefore be seated at the left of the patient's head, and arrange a footstool of suitable height so that she may support upon her left knee the weight to be carried. Her right hand is placed upon the patient's forehead, her left under the occiput, and once in position she must not relinquish her hold. In a patient with a spine of normal flexibility, and with upper incisors not unduly prominent, the tubes may be passed into the bronchial branches

and into the stomach without excessive pressure upon the teeth. The right-lateral posture, however, affords special advantages in œsophagoscopy and in the examination of the left bronchus. The tube is passed through the lower angle of the mouth (i.e., by the right upper molars), and is thus already furnished with a slight leftward deflection, which is especially valuable when the diaphragmatic portion of the œsophagus has to be traversed, slanting as it does towards the left side. The lateral posture, moreover, facilitates the drainage of saliva out of the corner of the mouth, and thus prevents its passage into the larynx and trachea. Both in the dorsal and lateral decubitus the straightening of the spine is rendered easier if the thighs are flexed upon the pelvis.

Manipulations.—Before commencing, all preparations must be complete. The surgeon, who either stands or sits according as he is dealing with a 'stool' or 'table' subject, places the instrument table at his right hand, with instruments within easy reach and arranged parallel to one another so that one may be picked up without disturbing the rest. Besides the extension tubes and forceps, he will prepare a dozen swabs on holders (very securely fixed), and a cup of cocaine and adrenalin. If a second assistant is present, he must be shown how to make swabs which are really secure, taught the names of the instruments, and instructed to hand them at a suitable angle.

The operator's right hand must remain free for delicate manipulations; the left, therefore, must hold the electroscope and perform the somewhat strenuous function of rotating the instrument round an axis transverse to the long axis of the tube. This rotation requires a fair degree of energy, for the patient's teeth must by no means be utilized as a fulcrum whereby to gain mechanical advantage.

It is of the essence of the direct method (and unless this principle is realized the method is fraught with many and great dangers) that the tubes must be introduced under visual control. In Brünings' instrumentarium will be found a set of gum-elastic mandrins intended to facilitate the introduction of the œsophagoscope in cases where the condition of the ostium is known to be normal and healthy—but even then only in the hands of the expert. For those who seek instruction in this short article, their use is inadmissible on all occasions.

We shall now proceed to consider the manipulations necessary (1) In tracheo-bronchoscopy (*a*) with the patient sitting, (*b*) with the patient lying; and (2) In œsophagoscopy.

1. *a. TRACHEOBRONCHOSCOPY WITH PATIENT SITTING.*—The patient being cocaineized, the operator firmly grasps in his left hand the electroscope, having pulled out the slide-stem to its full length if forceps are to be used, or leaving the slide 'home' if a fugitive examination alone is contemplated; in either case centreing and focussing the light to suit the circumstances (see p. 373). A suitable tube spatula is fixed, warmed, and lubricated, and its corresponding extension tube (perforated in the case of bronchoscopy) is also prepared and placed within easy reach. The mouth is gagged open, and the lips and teeth protected with a cloth or sheet of rubber.

As the spatula is introduced, the surgeon will see through its lumen the uvula first, and then, as he rotates the instrument more into line with the patient's long axis, the tip of the epiglottis. At this moment the first, and perhaps the only puzzling, difficulty arises. It must be remembered that at the approach of the instrument the laryngeal vestibule instinctively takes up a defensive attitude, and, by contracting, not only approximates its sides but also its anterior and posterior walls; that is to say, the epiglottis is drawn back, and the tips of the arytenoid eminences are drawn forwards almost under cover of the epiglottis. Thus the picture observed through the tube is of the posterior aspect of the arytenoids, and the tyro in bronchoscopy often falls into the error of

passing the tube down into the hypopharynx. Immediately, therefore, the tip of the spatula has passed the upper edge of the epiglottis, the act of rotation must be made, and the vocal cords will at once be brought into view. If now the patient be encouraged to breathe quietly and regularly, the spatula may be gently coaxed through the glottis during inspiration, and so soon as an inch or two of spatula has passed this point the strain upon the left wrist will be relieved. Where spastic closure occurs, it is only necessary to rotate the spatula on its long axis until its narrow lip can be inserted between the cords. I would emphatically urge beginners always to make use of two hands in these more delicate movements; that is to say, leave the levering work to the left hand, and with the right index and thumb hold the shaft of the spatula and gently push it downwards through the glottis. This bimanual method is of special importance in passing the œsophageal ostium.

Once the spatula is well in the trachea, an excellent view should present itself of the whole of that viscus and also of the upper segments of the bronchial tree; and if such a view (granted a healthy trachea) is not obtained, the operator may assume that the spatula is not truly aligned with the tracheal axis and that more leverage must be accomplished by the left hand. The carina is now painted with cocaine and adrenalin, the lamp-carrying portion of the endoscope is turned to the left, and the extension tube inserted. The latter is now gently introduced into the bronchi, easily into the right, with more difficulty into the left, which must slowly be straightened out by the advancing rigid tube. During this latter process the pulsations of the aortic arch, which crosses above the left bronchus as it leaves the trachea, will be felt by the operator. Sticky mucus is best removed by a rotary movement of the swab; and when the suction tube is employed to remove copious secretions, its tip should be dabbed gently upon the surface to be cleansed, otherwise the mucosa or granulations may obstruct the orifice. The suction apparatus can be hooked on to the operator's overall.

b. TRACHEOBRONCHOSCOPY WITH PATIENT LYING.—When the patient is lying upon his back or right side, the operator must stand up to start the insertion, and gradually find his chair as the tube comes down into its final horizontal position; his left arm will of necessity lie across the patient's face, knuckles uppermost. In a prolonged case it is rather tiring to keep the arm raised, but the rotary power of the wrist is very great in this attitude. The strain upon the raised arm may be avoided by adopting the left lateral posture for the patient, but this is disadvantageous on other grounds; and Brünings, who advocates this posture in some cases, subsequently turns the patient over, a manœuvre which, without plenty of assistance, is unsafe.

The anæsthetist stands at the patient's left hand, and must be warned not to obstruct the operator's view by inserting his chloroform tube into the line of vision at inopportune moments. The small mirror must be cleansed from time to time as expectoration is coughed upon it, and in all septic cases the operator should protect his eyes with spectacles. Slightly plus spectacles are advantageous from an optical point of view, and the small telescope to be obtained with Brünings' set is valuable in some cases.

No description is required of the passage of tubes into the bronchial branches—suffice to say that it is impossible to obtain a view of the whole of the eparterial bronchus without reflecting or refracting instruments.

2. ŒSOPHAGOSCOPY.—Œsophagoscopy is conducted on precisely similar lines to those of tracheobronchoscopy, and either local or general anæsthesia may be employed. It is held to be a more difficult and dangerous procedure than the latter, and many more accidents have resulted from it. There is no reason why this should be the case if the principle of constant visual control were rigidly

adhered to, and if all abnormal appearances were regarded as danger-signals. Formerly the blind introduction of the œsophagoscope guided by a mandrin was the rule; clearly such a manœuvre is a good deal more dangerous than the passage of the old flexible bougie, and that instrument has been responsible for its full quota of deaths. The form of Brünings' tube spatula renders the use of these mandrins quite superfluous.

The preparations are much the same as those for tracheobronchoscopy, except that the cocaine swab is carried into the hypopharynx instead of into the larynx, after the tongue and uvula have been painted.

As a general rule the right angle of the mouth is the easier route, and right lateral recumbency the most suitable posture; but in a patient with deficient upper incisors the mesial route is easy. The lip of the spatula is passed down behind the arytenoids, which are readily identified by their respiratory movements, and the instrument is wriggled down with a slight rotation upon its long axis until the cricoid constriction is seen. At this point surgical judgement comes into play, for it is through the forcible passage of this ostium that the majority of accidents occur. The ostium must be well and quietly examined, and if necessary a probe may be used with a delicate side-to-side movement to determine the exact position of the lumen. If a cocainized patient is requested now to make the act of swallowing, the ostium will momentarily open and the tube may be popped through. I strongly deprecate this manœuvre at the first examination of a case—until, in fact, the upper end of the œsophagus is known and proved to be healthy. This *tour de maître* has repeatedly given rise to accidents and mistakes, for the instrument is made to shoot suddenly past the very region where disease and small foreign bodies are most frequently located. I therefore would strongly urge the reader always to make the passage of the ostium by a slow, sliding movement, and under the keenest visual control. With the power of the left wrist the cricoid cartilage should be retracted from the spine, while at the same time the index and thumb of the right hand supply the very firmly controlled downward pressure, the two hands adding a slight rotation of the spatula to and fro on its long axis. The friction to be overcome really amounts to that resulting from the backward pressure of the cricoid against the tip of the spatula, added to that of the teeth pressing its butt-end forwards or to the side. This fact is made evident if too short a spatula is used on a long-necked man—it has happened to me to see the butt-end of the instrument unexpectedly slip on into the mouth, while at the same moment the tip has readily shot through the ostium precisely in the manner I wish to deprecate. Once the ostium is passed, the examination of the œsophagus in a normal patient is exceedingly easy, granted that the spine has been suitably straightened by flexing the thighs upon the pelvis. So soon as the thorax has been entered, several inches of an almost cylindrical hollow cavity are seen ahead of the instrument; and if this is not the case, one may assume that the instrument is not properly aligned and that the posterior wall alone is in view. The size of the lumen will be seen to wax and wane on inspiration and expiration respectively, and peristaltic movements may be observed; but closure of the lumen, except in the neighbourhood of the ostium and at the hiatus, may be regarded as pathological. The tube meets with but slight resistance at the hiatal opening, and seems almost immediately to enter the stomach, near the posterior wall of that organ.

CONTRA-INDICATIONS AND DANGERS.

In the presence of fixation of the jaw, and of marked lordosis of the spine, peroral œsophagoscopy and tracheoscopy are impossible. In the case of large, jagged foreign bodies firmly impacted in the larynx, less damage will be done by the very simple operation of laryngo-fissure (see LARYNX, MALIGNANT

DISEASE OF) than by fruitless attempts at peroral removal. Similar bodies in the trachea, and also highly friable bodies, are best attacked by the inferior method, i.e., after tracheotomy.

In general terms it may be said that there are no genuine contra-indications to the removal of foreign bodies from the air-passages. For example, the presence of septic pneumonia should hasten rather than delay the attempt at removal, and the same may be said of a case moribund from slow asphyxia. I would quote in the latter connection a case where, after secondary hæmorrhage following laryngectomy, the patient slowly sank and collapsed and was deemed by a skilled nurse to be dead. The passage of the tube showed that the patient had for some time been breathing through a small hole in the centre of a diaphragm of dry blood-clot occupying the lower end of the trachea. A few minutes after removal of the clot the pallor disappeared and the patient was practically well. In this, as in similar cases, there was pallor and no cyanosis. Even the presence of a large aneurysm is not a genuine contra-indication to tracheoscopy; for even should the tracheal rings have been absorbed, the bulging aneurysm with its wave-like pulsation can readily be seen, and its region studiously avoided; such a case entails precisely the same minute care as every case should receive.

Special dangers and difficulties may arise in the attempted removal of foreign bodies, and these must be weighed against the danger of leaving matters *in statu quo*, not forgetting that the *status* may at any time change, either through the shifting of the object, the penetration of the walls, or the onset of septic phenomena—and in this latter connection one may say that, of all the more common foreign bodies, decayed teeth are, more than any other, likely to set up septic pneumonia.

In all cases the dangers are minimized by the presence of tracheotomy and cricothyrotomy instruments, and in many cases it is best to lay bare the trachea as a preliminary measure. This is specially important where a foreign body too large to be drawn into the tube has to be withdrawn, naked, through the glottis. In removing a body from a bronchus, the utmost care must be taken that it is not cast adrift from the forceps and inhaled into the other bronchus, thus possibly putting both lungs out of play simultaneously.

For purely diagnostic purposes, the direct examination of the œsophagus must be approached with considerably greater caution than is necessary in the case of the trachea; the œsophageal picture is more difficult to interpret, and the mucosa far more delicate and hæmorrhagic. Cirrhosis of the liver entails the danger of profuse hæmorrhage from the lower section of the gullet, and aneurysm is generally regarded as a definite contra-indication. Certainly the tube should not be passed soon after the swallowing of corrosive poisons. The existence of fever spells danger, and if it is accompanied by persistent pain (not merely on deglutition) and surgical emphysema, mediastinitis must be dealt with *ad hoc*. The mortality from the removal of foreign bodies by œsophagotomy is very much greater than that following the endoscopic method. In a case of œsophagitis with fever which remains stationary or decreases, and where the history, symptoms, and skiagraphy leave the surgeon in doubt as to whether the case is, or is not, one of mere laceration, an expectant attitude may be adopted. Similarly, in doubtful cases occurring in patients with disease of the respiration and circulation, the surgeon should withhold his direct examination, and await more definite indications. This is a matter for the general surgical judgement, and it may be said here that more cases are lost from undue delay than from carefully conducted, but fruitless, examinations. The presence of malignant disease is no contra-indication to the method, granted that the tubes are inserted under visual control, and only down to, and not into, the diseased regions. I do not

know of any untoward result where these two principles—i.e., continuous visible control, and consequent avoidance of diseased areas—have been adhered to strictly.

NATURE, DETECTION, AND TREATMENT OF FOREIGN BODIES.

1. **In the Air-passages.**—From the surgical standpoint, foreign bodies may be divided into classes according to their physical qualities : for our purpose it will suffice to consider that they may be smooth, jagged or sharp-pointed, tough or friable, hard or soft, and particularly that they may swell on imbibing moisture. Some are septic at the outset, but all may set up septic phenomena. Statistical tables may be found of these various classes ; but seeing that at the present time only a small proportion of the innumerable cases occurring are being recorded, it is unnecessary to do more than allude to them.

It is more important to consider that the physical qualities often determine the course taken by the case. For instance, a pin lodged in a bronchus may cause no more trouble than a persistent dry cough ; but a bean in the same position will inevitably, by swelling, produce atelectasis of the lung ; while a septic tooth will speedily cause a spreading septic bronchitis ; so it comes about that in certain cases the presence of a small foreign body may be well tolerated for months or years, while in others severe dyspnœa on exertion is a prominent symptom, and in yet others, spreading septic bronchitis supervenes within a few days. I said above that all cases are in a sense urgent, but in point of fact quite a considerable proportion become chronic cases ; that is to say, a mere persistent cough or a bronchorrhœa exists which may be tolerated with but slight impairment of health for a long time ; but the condition is always associated with the danger of severe and fatal exacerbation. Where a foreign body has been impacted for a length of time in the bronchial tree, it is often surrounded by granulation tissue, and may even be hidden by a cicatricial stricture ; such cases may prove extremely difficult to treat, and should not be attacked without a more extended knowledge than can be gained from this article, the purpose of which is to prevent the occurrence of such cases by indicating means of immediate removal.

The symptoms of foreign body in a bronchus may be elusive. After the reflex cough following the initial aspiration, nothing may be observed for a day or two, when persistent cough and perhaps pain may result from the local irritation. Even when one lung is completely put out of play, cyanosis may not occur except on exertion. The recurrence of fits of coughing, with intense laryngeal dyspnœa, alternating with periods of ease, indicates a foreign body lying free in the trachea and occasionally blown up to the glottis. Such cases are fraught with special danger, and the patient must not be left by the surgeon until the condition is relieved.

The diagnosis in all these cases must be arrived at on general lines. The history, unfortunately, is often misleading, as a very large proportion of cases occur in young children. The chest is to be examined for unilateral impairment of movement ; for diminution of breath sounds and vocal resonance ; and dullness to percussion, indicating a spread of the bronchial inflammation to the periphery, must be sought for. Both diagnosis and localization may be determined by the *x* rays, which will also indicate the size and character of the foreign body where this is opaque to the rays. A negative result, either with the screen or the skiagram, is not conclusive, as statistics certainly prove ; and it must be remembered that the respiratory movements serve to obscure the outlines of the shadow. In many cases the *x* rays are of the greatest service not only in diagnosis but as an operative adjunct ; for the tubes and forceps may be passed, while a second observer watches their approach to the foreign body in the fluorescent screen.

By surgeons unaccustomed to direct vision methods, it may be taken as a wise rule that in small children all foreign bodies should be removed through a tracheotomy wound. Frequently the object is expelled as soon as the trachea is opened; and if this does not occur, it is preferable to work through a broad short tube rather than rely upon the peroral route and upon a 7 mm. bronchoscopic tube of some length. At all events the difficulties are such that, until expertness is gained, the trachea should be laid bare before commencing manipulations. In adults, also, the inferior route should be adopted where the foreign body is large and jagged, or where it is likely to break up when grasped by the forceps; and some authorities go so far as to say that such a body as a bean softened by a few days' retention should always be approached by this route. In the majority of adult cases, however, the peroral route will prove quite satisfactory. Before attacking any case the operator should, if possible, practise picking up through the tube a body similar in size, shape, and position to that in question. Such practice largely removes the difficulty which arises from the foreshortening of the bronchoscopic picture, and shows him in some measure how and where best to seize his quarry. An object such as a nail will generally lie point upwards, and this point must be drawn within the lumen of the tube before extraction is made. Great care should be taken not to lose hold of the object by fruitlessly attempting to drag into the lumen some portion of it which is too large to enter. The seizing and the extraction should therefore be made with the greatest care, and deliberation and special caution are needed at the moment when the glottis is to be passed.

As a general rule the mouse-toothed forceps will be found the most serviceable, but for seizing a pin the pair with flat blades set at a right angle should be used. In all cases the blunt hook is a serviceable instrument, enabling the operator to turn such an object as the large end of a collar-stud so that an edge presents and affords a hold for the mouse-toothed forceps. Beans are universally recognized as objects particularly difficult to grasp, more especially as with a little swelling they tightly fit the bronchus of a child.

In every case the ingenuity of the surgeon will be put to some test, but in the large majority he will be entirely successful. A few cases have baffled the most experienced of operators; and where the object is deeply seated, bronchorrhœa profuse, and granulations abundant, perhaps no more difficult manipulations can be met with in surgery. If the view is obscured by blood in spite of adrenalin applications and of the frequent use of the suction tube, the operation had best be abandoned temporarily; for experience shows that repeated and short attempts at removal are fraught with less danger than very prolonged manipulations—though in point of fact reactionary swelling of the larynx is rare, even in children. Prolonged attempts, in the presence of impaired respiration, have been followed by fatal collapse, whereas manipulations occupying ten to fifteen minutes seem to be tolerated quite well even in bad subjects. One of the chief difficulties to contend with is reflex cough; the carina, and especially the inflamed area about a foreign body, therefore, should be well cocaineized even under chloroform anæsthesia.

2. In the Œsophagus.—Bodies are impacted in the gullet by reason of their excessive size, or by the engagement of one or more sharp points or edges in the mucosa. A large mass of meat may be gripped tight in the œsophageal ostium and require some degree of traction for its removal. The commonest object, however, is a halfpenny which engages in the cricoid constriction. In either case difficulty in swallowing is experienced at a point easily localized by the patient and without accompanying pain. In the case of the coin, drink and well-chewed food may pass, and the obstruction be tolerated for many days. It is common knowledge that innumerable needles, nails, and so forth are

swallowed, and pass without trouble *per vias naturales*, or become impacted only in the rectum. When ingestion of such objects is suspected, the swallowing of a bolus of tenacious food is the recognized treatment, granted that pain is absent. Where penetration or laceration of the mucosa is indicated by pain, an endoscopic examination should be made. There are exceptions to this rule; the presence of fever and of surgical emphysema contra-indicates the use of the tubes; but I wish to suggest that the day has now passed when bougies should be used blindly in the hope that they may dislodge and thrust on a foreign body. Every doctor is aware of cases within his own hospital experience in which the blind use of œsophageal instruments has caused fatal consequences; and wherever pain suggests the presence of a sharp foreign body these manipulations should be considered inadmissible, it being a mere chance whether or no fatal mediastinitis is to result from their employment.

In the case of a coin recently impacted at the cricoid, and located by *x* rays,

Fig. 31.—Fishbone in œsophagus. Actual case reconstructed to illustrate the danger of bougie or umbrella-probang when used blindly.

Fig. 32.—Fragment of bone embedded at œsophageal ostium. Actual case reconstructed to illustrate uselessness of bougies.

the coin-catcher should prove a harmless weapon; but in the case of sharp bones, dentures, and so forth, neither the bougie nor the umbrella-probang should be employed.

Fig. 31 depicts a fishbone two inches in length which was removed with the greatest ease by the direct method from an intelligent patient who was suffering great pain after swallowing "a small fishbone." For the purpose of the sketch it has been placed in the œsophagus of a cadaver in the position which it occupied in the actual patient. A glance will show that attempts to remove this foreign body with the umbrella-probang must have ended in failure or in severe laceration.

Fig. 32 is the diagrammatic representation of a fragment of pigeon-bone deeply embedded in an ulcer just below the cricoid constriction, from which it was readily

removed by the direct method. The object has been so far pressed into the mucosa of the left side of the œsophagus as to be almost invisible through the lumen of the tube spatula. The passage of a bougie would merely have pressed it deeper into the inflamed tissues.

In many cases the bougie and probang can no doubt be employed with safety and success, either to thrust the foreign body into the stomach or to extract it; but it may fairly be said that in no case, with the possible exception of a coin quite recently engaged in the cricoid constriction, can the blind method be claimed as perfectly safe; while if it fails to relieve the patient, it can merely indicate the seat of the impaction and nothing more. I have seen even a bolus of meat and gristle so securely grasped by the sphincter muscles of the ostium that considerable traction was required to withdraw it. It was so placed that had a bougie been blindly passed, its tip must inevitably have been directed into the larynx.

Large, rugged, sharp-pointed bodies are better extracted by œsophagotomy (if impacted high up) or by gastrotomy (if in the lower segment). Chevalier Jackson claims that anything that has passed down through the ostium can be extracted by the same route; Killian is of the contrary opinion.

At the same time it must be remembered that the mortality after œsophagotomy is fairly high. An incision is made at the anterior edge of the left sternomastoid, and the side of the trachea is reached after slitting the deep fascia on a blunt (e.g., Kocher's) director, and retracting the thyroid gland and great vessels to either side of the field. The recurrent laryngeal nerve in the angle between the trachea and œsophagus must be respected, and the wall of the œsophagus, recognized by its longitudinal muscle fibres, is then drawn forward and opened by a longitudinal incision, and the finger introduced. After removal of the foreign body, the wound in the viscus is carefully closed by three layers of Lembert sutures. A perfectly watertight closure capable of resisting the strain of vomiting and deglutition is difficult to obtain; therefore the neck wound should be kept widely open and packed with gauze until granulation has created a barrier against spreading sepsis—which is the cause of the high mortality after this operation.

The very large majority of impacted foreign bodies are found in the region of the ostium*, but some occur about the tracheal bifurcation, some near the diaphragmatic hiatus. In the latter event gastrotomy may be necessary, and removal conducted with the aid of peroral or of retrograde œsophagoscopy. Retrograde œsophagoscopy should be conducted only after suturing the stomach wall to the abdominal parietes. If the finger is used, the stomach wall should be secured round the base of the index finger with a purse-string suture, and the object displaced into the stomach by cautious palpation.

When doubt exists as to the wounding of the œsophagus, either before or during endoscopic manipulation, only iced and sterilized liquid food or jelly should be given, and milk is better avoided. Small doses of 3-vol. peroxide may be sipped every hour.

This article, which deals at some length with certain details, and even repeats more than one point, in fact only touches the fringe of what has now grown to be a subject of considerable surgical importance. There are many different systems of tube construction and of illumination, and in America, for instance, where the admirable work of Chevalier Jackson is followed, the illumination is obtained from a minute lamp placed at the distal end of the tube. This article does not purport to serve as a primer for the young bronchoscopist (he will find an admirable work in Brünings' *Direct Laryngoscopy, etc.*, translated by Howarth), but as a practical guide to the general surgeon, in charge, say, of a

* See Burger—StClair Thomson, *Diseases of Nose and Throat*, 1912.

small colonial hospital, who has many more important duties to perform ; and if it be written intelligently, it should, coupled with a set of instruments, enable him to deal endoscopically with nine out of ten cases of "acute foreign body." I venture to repeat that the subject is not a highly technical, nor in any sense an occult, one ; and that any skilful surgeon with a steady hand and keen vision may attack the great majority of these cases with confidence, granted he adopts a certain frame of mind—one, that is to say, of extreme precision, deliberation, and caution.

FOREIGN BODIES IN STOMACH.—(See STOMACH, FOREIGN BODIES IN.)

FRACTURE SPRAINS.—(See SPRAINS.)

FRACTURES.—(See also under NOSE, JAW, SKULL, SPINE.)

I.—GENERAL PRINCIPLES.

The changes which have taken place in recent years in the treatment of fractures may be traced :—(1) *To the use of the Röntgen-ray shadow* for revealing more or less accurately the position of the broken ends of a fractured bone before and after treatment ; (2) *To the introduction of the antiseptic method* of treating wounds, whereby, when efficiently carried out, the injured parts can be exposed to view and directly dealt with, without undue risk to the patient ; (3) *To the adaptation of massage and movement* to the treatment of fractures, a method which has been worked out by Professor Lucas-Championnière in Paris.

1. The *Röntgen rays* when employed to examine injured bones and joints have shown many points of much interest and value. Besides establishing or refuting a diagnosis of fracture in doubtful cases, they have revealed the presence of fracture where it was not supposed to exist. They have, moreover, taught us that the ends of the broken bones are seldom in accurate apposition even in cases where the functional results have been considered satisfactory ; while in cases where these results have been unsatisfactory, they have shown why it has been so. Although surgeons were at first shocked to find that their efforts at reduction and retention were less effectual than they had supposed, they have learned, and are still learning, to distinguish between imperfect union which is functionally important and may require operation, and imperfect union which is functionally unimportant and may be ignored.

2. In like manner, the *open method* of dealing with simple fractures has led to a clearer knowledge of the relation of parts in certain cases of fracture, and thus has enabled us better to distinguish the few cases that require operation from the many that do not.

For the majority of the members of the medical profession who are engaged in general practice, the use of a Röntgen-ray apparatus is not easily obtained. Comparatively few, moreover, have sufficient time or suitable opportunity to enable them to practise antiseptic surgery with that certainty of success which alone would justify their opening up simple fractures. It is, however, none the less important for the general practitioner to be able to recognize the cases that are likely to require these special procedures for diagnosis or treatment : he can then call in the help that he needs. Fortunately, such cases are comparatively rare, and we shall try, when indicating what seems to be the best method of dealing with the various fractures of individual bones, to point out those cases for which the services of a Röntgen-ray specialist, or hospital surgeon, are likely to be required.

3. With regard, however, to the *massage and movement method* of treating fractures, the case is different. With very few exceptions, every fracture in the

body can have this method applied to it with much benefit to the patient, the principles of the method can be easily understood, and the practice can be learned by any member of the medical profession without going through a special course of study. Medical men in busy practice may not be able to give the full amount of time required, but when they understand the advantages their patients will gain in shortened time off work, and in improved functional results afterwards, they will find ways of securing for their patients at least a large proportion of the full possible benefit.

The methods of treating bones of the extremities which were universally accepted twenty years ago, and are still practised by many surgeons, were based upon the supposed necessity of absolute immobility of the broken ends of the bone until the callus was well formed. This supposed necessity for immobility was looked upon as the first principle, and as a corollary to it there stood the rule that the apparatus which fixed the broken ends of the bone should at the same time fix the joint above and the joint below.

The period during which this immobility was maintained varied from about three weeks to three months or longer, depending upon the bone broken, and the age and healing power of the patient. After the bones had united, the return of the limb to functional usefulness was taken into consideration, but not before. It was then found that the weakness and stiffness of the muscles, and the limited range of movements of the neighbouring joints, often more than doubled the period of functional disability of the injured limb which the treatment of the fracture had already involved. In many cases, the functional disability was permanent. These troubles were, however, considered to be inevitable consequences of the fracture—evils indeed, but less than those associated with the non-union which would have resulted from too early release from splints. The bad results obtained by prolonged immobility form a striking contrast to the good results obtained by immediate operation in the hands of competent hospital surgeons, and on this contrast has been founded the main argument for frequently operating in recent simple fractures. Fortunately, however, an improvement in the non-operative method of treatment now enables the general practitioner to obtain functional results equal to those obtained by operation in a large number of cases in which prolonged immobility ended in permanent disability. We know from the experience of Professors Lucas-Championnière and Guérmonprez and others in France, and from that of Sir William Bennett, Mr. Wharton Hood, and many others in this country, that the supposed axiom of the necessity for absolute immobility to insure bony union was not an axiom at all. It was only an erroneous opinion, and we now have other opinions which seem to be more securely founded, and on which is based a practice which gives better results. In formulating these opinions, we shall not follow the exact views of any one of the surgeons to whom we owe them, since they differ from one another in detail. We shall try, however, to state briefly the general conclusions at which we have arrived after studying the most important published works upon the subject, and after having had personal experience of the methods in hospital and private practice.

These may be briefly stated as follows:—

1. Absolute immobility of the broken ends of bone is not essential to bony union. The ribs unite in spite of the movements of respiration, and wide experience has shown that the slight amount of movement necessarily involved in the daily massage of a fractured limb, and in the daily active and passive movement, for a few minutes at least, of the adjacent joints, seems to hasten rather than hinder the formation and the solidification of the callus.
2. Extravasated blood in joints and among muscles and synovial sheaths leads to adhesions in its neighbourhood, as if it were in itself a source of irritation.

3. The use of massage in the form of stroking and gentle kneading, combined with occasional movements, is in several ways beneficial in the treatment of fractures. These measures not only aid the actual union of the bones, but help in the absorption of effused blood and serum, restrain if not prevent the formation of adhesions among the soft parts, and maintain the nutrition of the muscles. They therefore simultaneously hasten union and prepare the limb to return to functional use almost as soon as the bones are united.

4. Splints, and other retentive apparatus, including extension, are required more to prevent mal-union than non-union, and hence are called for especially where the weight of the limb or muscular action is likely to lead to a bad position during healing.

5. On this account, retentive apparatus should, as far as is consistent with its main object, not restrain the movement of the adjacent joints, nor impede the circulation of the limb, and it should be dispensed with as soon as possible.

6. The manipulations necessary for the massage and movement treatment of fractures can be successfully carried out by anyone who will take the trouble to understand the object of the manipulations, and who will be careful to avoid causing pain when he handles an injured and very sensitive part.

As massage and movement are, for the reasons just given, so important in the treatment of fractures, it seems advisable that we should explain their use in a general way before we discuss the diagnosis and treatment of particular fractures.

OBJECTS OF MASSAGE.—In a recent fracture, say from a few hours to a few days after the accident, the object of massage is to diminish the swelling, to allay muscular spasm, and to soothe pain. After acute symptoms have subsided, the object of massage is to stimulate the circulation of the limb, to disperse accumulation of blood and of serum—one or both—and to maintain the nutrition of the muscles, nerves, and soft parts generally. That massage has the power of fulfilling these objects after recent and old-standing injuries to the soft parts has been proved by clinical experience, and by experiments made upon animals.

Methods of performing Massage after Fracture.—In recent cases, after the patient has been put to bed, or otherwise placed in the most comfortable position which the circumstances permit, the affected limb must also be made comfortable. It should be laid on a pillow on the operator's knee, or merely on the bed, and arranged so that the operator can have easy access to it. The injured limb must be steadied by an assistant or by the operator with one hand while he massages with the other.

Where there is much pain, and especially where there is great spasm of the muscles which pass over the broken bone, a small hypodermic injection of morphia will be an advantage. Many patients are much relieved by fomentation of the limb with hot water. After this has been done, the skin must be dried gently with a soft towel, and then dusted over with some fine powder to facilitate the rubbing. Finely powdered talc is recommended by Dr. Dagrón, but finely powdered boracic acid, toilet powder, or ordinary flour, will serve the purpose as well. The operator begins by gently stroking the limb, beginning on the proximal side of the injury and following the course of the veins towards the heart. In doing this he will employ as broad a surface of his hand and fingers as he can, and he will be guided as to the amount of pressure he uses by the sensations of the patient. *He must not cause the patient pain.* He will find that after a little he can extend the area of his rubbing, and press a little more firmly without causing pain, than he could at first. He will not be able to press over the seat of fracture itself, but may with advantage stroke towards it from below upwards. Where there is great tenderness of the injured limb, the

massage should take the form of a series of light pressures successively applied from below upwards, and regulated as to strength by the sensations of the patient as before. Attention should next be turned to the muscles, and as the object at this stage of the work is to soothe and allay spasm, the simple rule is to massage all the muscles which pass over the seat of fracture or which act upon the broken bone. According to the degree of tenderness, the massage of the muscles will vary as before, from a series of caress-like touches to more firm pressures, or even very gentle kneading. Each muscle, or group of muscles, is taken by itself, and its fibres are followed as nearly as possible in the direction of the venous return. This should be succeeded by a repetition of the upward strokes, or light surface pressures, with which the process began. The length of time required varies from ten to twenty minutes, according to the circumstances. It will often be found that the sufferings of the patient have been so much relieved, and the muscular spasms so much reduced by the massage, that it will be possible to dispense with a general anæsthetic in order to complete the diagnosis or set the fracture. Even, however, when a general anæsthetic is required, this preliminary massage should be employed to reduce effusion, before splints are applied. If movements are permissible they are then performed, and after that the retentive apparatus should be applied.

In some cases these procedures should be repeated daily at first, in others at intervals of one or more days, the splints being taken down for the purpose, and afterwards reapplied. The limb should be steadied as at first, but with less precision as the muscular spasm becomes less and the ensheathing callus more solid.

After the acute symptoms have passed off, the stroking movements are firmer and more extensive in their sweep; their object being, as before, to empty the veins and lymphatics, and so to stimulate circulation, and to get rid of any swelling which may remain. Where definite collections of blood or serum are present, the pressure may be applied to them more energetically so long as no pain is caused, either by a kneading or by a circular "milling" movement of the hand or fingers. The stroking movements should be repeated from time to time to empty the vessels. Attention should then be paid to the muscles. The object should be to gently stimulate the muscular fibre by pressure and kneading movements carried along from one end to the other. The sitting will be brought to a close in every case by a number of stroking movements.

When the fracture involves a joint or passes close to it, special attention should be paid to the ligaments, synovial membrane, and synovial sheaths, while stimulus to the seat of fracture itself should be avoided. The object is to get rid of effusion and prevent adhesions. Where cancellous tissue, well supplied with blood from both sides, is broken, we do not fear non-union. There is, however, risk of excess of callus, especially in a young subject. Hence the advisability of avoiding any stimulation to the seat of fracture by massage. This would increase the amount of callus and so embarrass the movements of the joint. When the broken part of the bone is within the capsule of a joint, one of the broken portions may have a very poor blood-supply, and then of course non-union will be the risk, but this seldom occurs except in the hip-joint, and not often there.

MOVEMENT AS PART OF THE TREATMENT.—Some surgeons have asserted that it is practically impossible in the treatment of recent fractures to restrict passive movements within limits that do no harm. The extensive experience, however, of Professor Lucas-Championnière and others has proved that this assertion has no foundation in fact. Passive movements should, however, be understood to mean movement produced by the surgeon's muscles and not resisted by those of the patient. It will be of interest to contrast the effects of the two

kinds of movement, in order that we may to the best advantage make use of each in the treatment of recent fractures. Active movement can hardly fail to be the more effective agent in maintaining the nutrition of the muscle and of the limb generally. In so far, however, as the action upon the joint is brought about by a strain along the line of the tendons, and not by a force applied from the outside, there will be a greater tendency to displacement of the broken ends of bone in active than in passive movement. For this reason passive movements will often be permissible at an earlier stage, and their range of movement will be relatively greater until well on in the treatment. Passive movements will therefore be especially useful in preventing the formation of adhesions which bind muscles and nerves to one another and to the bones at the seat of fracture, and which cause synovial surfaces to adhere within joints and synovial sheaths. Each kind of movement, however, will have some of the special therapeutic action of the other; thus, active movements will help to prevent stiffness, and passive movements will help to maintain nutrition. Moreover, many patients who are afraid to move a joint in the neighbourhood of a fracture will yet permit of gentle passive movement, and will be encouraged to make voluntary efforts when they find that passive movement does not cause pain. Both forms of movement require to be used with care, so as to avoid displacement of the broken ends of the bone, and pain or serious discomfort to the patient.

One possible advantage of active movement in the treatment of fracture not sufficiently appreciated, is the ability to utilise the patient's voluntary effort in the reduction of displacement due to muscular contraction. After the muscles have been soothed by massage, the patient can sometimes voluntarily replace a displaced bone. This use of voluntary action may perhaps be best illustrated in a case of Pott's fracture with marked displacement outwards of the foot by action of the peronei so as to stretch the skin over the internal malleolus. If the surgeon tries to pull the foot into position, the antagonistic muscles will start up in opposition and prevent him from doing so, while the patient will be caused very severe pain. If instead of this the surgeon gently steadies the foot and encourages the patient to lift it inwards, he will be surprised to find how much ground will be gained. The surgeon may then cautiously supplement the active movement with a little pressure in the same direction. Apparently the voluntary effort ensures relaxation of the displacing muscles along with the contraction of those that are helpful. The same method may be applied in a few other cases, working on the principle that when a group of muscles in spasm causes displacement, a relaxation of these contracted muscles will be induced by a voluntary contraction of the opposing group.

Is there any need for a Trained Masseuse?—Professor Lucas-Championnière finds that almost any intelligent person can be taught to carry out the manipulations requisite for his method of treatment. In the wards of the Edinburgh Royal Infirmary many cases have been treated entirely by second and third year students, with quite satisfactory results. There seems, therefore, no reason why every medical man should not be able to practise at least Professor Lucas-Championnière's method, either directly, or indirectly through assistants to whom he has given a few lessons. If the treatment be applied first to a Colles's fracture, it can afterwards be extended to others.

THE USE OF SPLINTS.—When the massage and movement treatment is applied to fractures, splints are used not so much to ensure immobility as (1) To prevent deformity; and, while pain on movement lasts, (2) To give support to the seat of fracture and adjacent parts.

1. *To prevent Deformity.*—An injurious degree of deformity, although not liable to occur in every case of fracture treated without splints, is still to be

fearcd in two groups of cases : (a) In the fracture of the shafts of long bones where the skeleton of the limb—either one or two bones—is broken in the middle two-fourths ; or (b) Near the articular ends of long bones, when the short fragment is considerably displaced by muscles.

a. In the first group are fractures of the shaft of the femur and humerus, or of both bones of the leg or forearm. In these injuries the joints above and below the broken bone may with advantage be supported for the first few days in order to relieve muscular spasm and consequent pain ; but after that the joints should be left free, so that the patient may make occasional voluntary movements.

It follows from this view of the function of splints when used along with massage and movement, that so long as deformity is prevented the splints should not constrict the limb and thus hinder circulation, and should not fix the neighbouring joints and thus hinder occasional voluntary movements.

b. In the second group are fractures of the surgical neck of the humerus high up, and fracture of the femur just below the small trochanter or just above the condyles. In cases such as these the fragments which can be controlled must, by the aid of splints, be kept in line with the other fragment which cannot be so controlled. In such cases the splint must fix the joint nearest to the seat of fracture, but it should, with due precaution, be loosened from time to time for massage and movement, beginning as soon as the parts are sufficiently united to make that safe.

2. The other use of splints still of value is to *give support*. There are many fractures in which there is little or no fear of deformity should splints not be used, but yet in which the patient suffers great pain and discomfort if the injured part be not adequately supported for the first few days. Colles's fracture is a case in point. If by extension and manipulation the deformity can be reduced, there is not much likelihood of its returning ; yet the patient generally welcomes the support of a splint to the wrist and hand for some days at least, and for this purpose a splint is of service.

THE USE OF EXTENSION.—However valuable massage may be in soothing a spasm, and voluntary effort in relaxing it, or however useful splints may be in maintaining a good position, obtained under anæsthesia or otherwise, there are cases in which continuous extension, by weights or elastic cord, is indispensable to obtaining the best possible apposition of the broken ends. These cases are those in which powerful muscles are involved, and in which it is possible to antagonize the displacement by a direct pull. The best example is the displacement of over-riding caused by the muscles of the thigh in an oblique fracture of the femur. The steady, continuous pull of a well-adjusted weight tires out the muscles, and diminishes, if not completely overcomes, the over-riding. The amount of weight employed will correspond with the strength of the muscles to be antagonized, and will vary from two or three pounds in a child to perhaps twenty pounds or more in a strong man. It is seldom necessary, however, to keep up the extension for more than a fortnight, although the splints may be required for much longer. More will be said about extension in connection with the fractures of bones of the lower limb.

THE DIAGNOSIS OF FRACTURES.—Although the well-recognized signs and symptoms of fracture—deformity, unnatural mobility, crepitus, want of power, great swelling, irregularity palpable in subcutaneous bones—are sufficiently well known to every student of medicine, the relative importance of the various signs and symptoms in the diagnosis of individual fractures is perhaps not sufficiently appreciated.

The surgeon should, if possible, investigate every case of fracture systematically, employing successively his "ears, eyes, and fingers." By so doing,

he will often spare the patient much pain, and at the same time be able to make a more accurate diagnosis than by the common method of beginning with the fingers and following or not with the eyes and ears.

History of the Accident.—It is important to obtain as minute details as possible of the way in which the accident has happened. Care should be taken, for instance, to find out if the patient fell because the bone had given way, or if the bone had been broken because the patient fell. If any direct injury or strain were the cause of the fracture, an effort should be made to ascertain as exactly as possible how the force was applied to the bone.

Inspection.—The shape and attitude of the limb will often be pathognomonic. This is especially seen when the shaft of the femur or humerus is broken, or both bones of the forearm or leg. Moreover, very valuable information will often be obtained by asking the patient to cautiously move the affected limb. As the result of such an effort we can sometimes exclude fracture by seeing what the patient can do, as well as confirm the probability of a fracture by seeing what he cannot do.

By *Manipulation and Measurement* the points we can make out are : irregularity of outline (including separation of portions of bone, and change of shape due to impaction) ; mobility, presence of crepitus, shortening, and the presence of tenderness when the injured spot is pressed upon or moved by pressure at a distance. It is not necessary that we should obtain all the characteristic signs in every case ; one sign is often sufficient, and in the discussion of the different fractures, attention will be drawn to the signs which are of most value in each case. Sometimes the swelling and muscular spasm may make the diagnosis difficult. If after diminution of swelling and spasm by massage there is still uncertainty, a general anæsthetic should be given. If the anæsthetic should not enable the surgeon to establish his diagnosis, a Röntgen-ray photograph should be taken. Apart from the use of the x rays as a guide to treatment, an x -ray photograph is important in all cases where there may be a question of compensation or 'damages.'

General Indications for Immediate Operation :—

1. Where marked angular deformity cannot be remedied under an anæsthetic or prevented from returning under the method of treatment adopted. This is especially important in the lower limb.

2. Where crepitus cannot be elicited under an anæsthetic, although the fragments are movable. This indicates that the broken surfaces are drawn apart by muscular action or are separated by soft parts, and will therefore probably unite by fibrous tissue only.

3. Where, a joint being involved, the movements are likely to be impaired by the presence of bone fragments or by alterations in the relations of the articular surfaces which cannot be otherwise remedied.

4. Where there is an excess of extravasated blood causing great tension in the limb.

5. Where there is evidence of injury to an important nerve or blood-vessel at the seat of fracture.

General Contra-indications for Immediate Operation.—Even in cases which might be otherwise suitable for operation, a surgeon would probably decline to operate :—

1. If the bones were probably brittle from old age or other cause.
2. If the patient's constitution were seriously impaired by disease or alcoholic excess.

3. If septic abrasions of the skin near the fracture were present, for in that case the wound would almost certainly become septic. In the case of compound fractures, the position of the bones may be rectified and maintained

sufficiently without plating; or silver wire, which is not irritating, may be used. In some cases the risk of sepsis can be obviated by the use of antiseptic measures. Should they be successful, plating, if required, may be carried out after an interval of three or four days.

Most Suitable Time for Operation when one is deemed necessary.—There is an advantage in waiting for two or three days after the accident. By that time a protective reactionary congestion will have set in at and near the seat of fracture, and shock will have passed off. From the fourth or fifth day onwards, however, replacement of fragments becomes progressively more difficult, owing to the formation and strengthening of adhesions.

CHOICE OF APPARATUS.—The changes which are coming over the treatment of fractures are not so much in the direction of new forms of apparatus as in modifications of the apparatus which have been in use for some time. Almost every hospital or school of surgery has its own form of retention apparatus with which good results have been obtained. In the pages which follow, an effort will be made to indicate the forms of apparatus which seem to be the most applicable to general practice, and the best adapted to the application of massage and movement. Under the heading "Massage and Movement" we shall follow for the most part the directions given by Professor Lucas-Championnière and his pupil Dr. Dagon.

DELAYED UNION.—This term is applied to a slow development of bone in the callus, and is due sometimes to deficiency in the general health of the patient, sometimes to want of active circulation at the seat of fracture. It is less likely to be met with under the massage and movement treatment than when the circulation of the parts is interfered with by prolonged fixation in splints. The indication for treatment is to stimulate the circulation at the seat of fracture, and this may be done in several ways. One of the best and simplest is to produce passive congestion by applying round the limb above the fracture an elastic bandage tight enough to retard the venous return and cause some swelling and bluish discoloration of the limb below. Formerly the parts below the fracture were supported with a bandage, but this is not necessary. The bandage may be kept on for about twelve hours out of the twenty-four, preferably at night. This method was introduced by the late Owen Thomas under the title of "damming" in 1878, but was not much used until it was independently discovered and advocated some years later by Professor Helferich. Another method which Owen Thomas practised with success is described by him as "hammering." It may be performed under an anæsthetic, at intervals of about a week, by wrapping the seat of fracture in a towel and beating it with a hammer or mallet; or, without an anæsthetic, by daily percussion for a few minutes as firmly as the patient can bear. "Hammering" can be best applied to subcutaneous bones, but it may be also applied to those that are clothed with muscle, care being taken not to damage nerves or large blood-vessels. "Hammering" and "damming" may be used with advantage together. Forceful rubbing of the ends of the bones against one another, with or without an anæsthetic, may be used independently, or to supplement the "hammering" or percussion. Professor Bier has obtained very good results in both delayed and non-union by the injection of the patient's own blood at the seat of fracture. By means of a strong 30-c.c. syringe armed with a hollow needle, from 15 to 30 c.c. of blood are withdrawn from a vein in the patient's forearm. The needle is thereafter thrust into the seat of fracture, and the blood is injected between the bones and as far as possible under the periosteum. All necessary precautions are of course taken to render the procedure aseptic. When these measures fail, operative methods will have to be employed.

II.—TREATMENT OF PARTICULAR FRACTURES.

FRACTURES OF THE CLAVICLE.*

The Middle Third is the most common situation. The break is caused occasionally by direct, but more frequently by indirect, violence resulting from a fall on the shoulder or outstretched arm. This form of injury seems to twist the clavicle, the strain acting on the bone through the medium of the conoid and trapezoid ligaments.

The history of this form of injury, with subsequent pain about the clavicle, and inability to use the arm, is important. The attitude of the patient in a recent case is characteristic. The elbow of the affected arm is supported with the other hand, and the patient inclines his head towards the broken bone. If in a suspected case the patient can easily abduct his arm, there will probably be no fracture. Fracture is probable if there be great swelling over the centre of the clavicle, although the patient had fallen on the tip of the shoulder. If swelling be slight, the irregularity of the subcutaneous aspect of the bone may be visible. If the swelling masks the condition of the bone even to the touch, the surgeon should move the outer end either directly or through the medium of the shoulder, while with his other hand he steadies the inner part of the bone. In so doing, he will elicit crepitus or abnormal mobility.

TREATMENT.—Should it be important to avoid any unsightly irregularity at the seat of fracture, the patient must be kept in bed, lying upon a firm mattress with a pillow between the shoulders, the arm being supported against the side by a bandage or sling. In this position the trapezius is relaxed, and the weight of the arm brings the broken ends into apposition. None of the appliances which have been devised to prevent the over-riding of the broken ends during ambulant treatment have succeeded in their object. They have all given results good as regards function, but imperfect as regards apposition. The results are no better than those which have been obtained without apparatus. These remarks apply to forms of apparatus in which an axillary pad is used to keep out the arm, to the Sayre plaster method and its modifications, in which the upper part of the humerus is erroneously supposed to be so firmly fixed that it can be used as a fulcrum to lever the shoulder backwards, and to the more or less complicated bandage methods. In a recent case the pain will be soothed by hot fomentations and by massage. The weight of the arm should be supported by a sling tied over the opposite shoulder. Where there is much pain, in addition to the sling, rest in bed or a broad bandage holding the arm against the side for a few days will be indicated.

Massage and movement should be employed daily for the first week, every second day for another week, and at longer intervals for the third week. The sittings should take about twenty minutes at first; afterwards a little longer. Massage the muscles acting upon the broken bone, i.e., trapezius, sternomastoid, pectoralis major, and deltoid; also the soft parts near the bone, and the bone itself, to soothe it. Passive movement of fingers, wrist, elbow and—gently—of shoulder at the beginning of the earlier sittings. On the second day and onwards allow active movement. At first this should be limited, as regards the shoulder, to a gentle swinging movement, and to gentle movements of the other joints. About the fifth day active movements of the shoulder may be permitted in all directions.

The sling which supports the arm should be worn under the shirt for the first week, after that over the clothes. It will probably not be required after three weeks.

* The views given as to causation are those of Professor Bennett, of Dublin.

The Outer End.—

a. Beyond the Conoid and Trapezoid Ligaments. Caused by a blow upon the back of the shoulder, due to a fall or otherwise. Diagnosis is established from the history, pain on movement, and crepitus.

TREATMENT.—There is no downward displacement, but the shoulder tends to rotate forwards; hence the figure-of-8 bandage should be applied to keep the shoulder back where appearance is of importance. Use massage, movement, and a sling as for fracture of the middle third, except that there will be less massage and more movement.

b. Between the Conoid and Trapezoid Ligaments. Caused by a downward blow upon the outer end of the clavicle. The clavicle is thought thereby to be broken across the coracoid process. Diagnosis as in (a).

TREATMENT.—There is no tendency to displacement; treat as for fracture of the middle third.

The Inner Third.—Caused by force applied along the line of the bone. Diagnosis is based upon the history, pain on movement, swelling of the soft parts, irregularity of the orifice, and crepitus.

TREATMENT as for fracture of the middle third.

FRACTURES OF THE SCAPULA.

These are caused by severe crushing of the thorax, and are generally accompanied by fractures of the ribs. There are dyspnœa and much pain on account of the large muscles which are involved and which are thrown into spasm at first. Diagnosed by the history of the injury, spasm of the muscles of the shoulder, irregularity of the subcutaneous parts of the bone, and crepitus on movement.

TREATMENT.—Massage the swelling and the muscles of the shoulder and upper part of thorax. In the interval, support the scapula by a bandage round the chest, and steady the arm with a sling. Fractured ribs are no contra-indication to massage. Adhesive plaster, if applied to the chest on account of the broken ribs, will support the scapula also, and massage can be carried out over the plaster. Massage should be daily at first, and at longer intervals afterwards. Passive movements of the shoulder while the scapula is steadied should be begun as soon as spasm has passed off. Active movements of the fingers and elbow should be encouraged early, and of the shoulder as soon as the patient can perform them without pain.

Fracture of the Acromion Process.—Caused by direct violence, a blow, or a fall upon the shoulder. Diagnosed by the history of the injury, drooping of the arm and shoulder, and inability to use the deltoid; local tenderness and crepitus.

TREATMENT.—The elbow should be supported as follows with an elastic webbing bandage three or four inches in width. Prepare pads of wool for the outer third of the clavicle and point of the elbow of the injured side and for the axilla of the opposite side. Now while an assistant raises the elbow of the injured side and holds the pads in position, the surgeon makes a series of figure-of-eight turns with the elastic bandage. Beginning at the opposite axilla he crosses the shoulder-pad, runs down under the elbow, up to cross the shoulder-pad again, and thence goes back to the axilla. A light strain on the elastic is sufficient. Massage can be employed to some extent without disturbing the bandage, but the latter can easily be removed and replaced every few days for movement, and it may be dispensed with in two or three weeks. Besides the elastic support, a bandage or sling to steady the arm is advisable at first, and massage and movement as for fracture of the main bone.

Fracture of the Coracoid Process is very rare, and is due to direct violence. The diagnosis is difficult. It may be suspected owing to pain on movement which involves the coraco-brachialis and biceps muscles, and may sometimes be established by crepitus and pressure over the coracoid process. An *x*-ray photograph is advisable in this and all other injuries about the shoulder where the diagnosis is doubtful.

TREATMENT as for fracture of the acromion process.

Fracture through the Neck of the Bone.—This is a very rare injury, and is important because the symptoms resemble those of downward dislocation of the humerus. It is caused by direct injury. The symptoms are like those of a downward dislocation of the humerus, with the difference that the flattening of the shoulder and lengthening of the arm can be overcome by gently drawing the arm away from the side and then lifting the whole arm upwards. Crepitus will be felt as the parts return into position.

TREATMENT as for fracture of the acromion process.

FRACTURES OF THE HUMERUS.

Fractures at the Upper End.—*General Remarks.*—After a severe injury to the shoulder, the exact diagnosis may be a matter of great difficulty. Besides fracture or dislocation of the upper end of the humerus, or both, there may be present fracture or dislocation of the outer end of the clavicle, or fracture of the acromion process.

A history of the accident must be obtained if possible. Then the various methods of procedure already mentioned should be carefully followed out. If, after the muscles have been soothed by massage, the diagnosis is uncertain, it is better to give a general anæsthetic. By the relaxation of muscles thus produced, and by the more free handling which is then made possible, the diagnosis may be established, and at the same time the treatment may be begun by the reduction of a dislocation or the setting of a fracture as the case may be. If, as may sometimes happen, a diagnosis should not be possible under a general anæsthetic, two courses are open: to have an *x*-ray photograph taken, or to reduce the swelling rapidly by massage and to repeat the effort at diagnosis in a day or two; or perhaps to employ both methods.

Malposition or adhesions are the two main reasons why, after fracture of the upper end of the humerus, the patient may never regain a proper functional use of the shoulder. (1) The upper fragment is in some cases markedly tilted upwards and outwards (abduction) by the action of the supraspinatus muscle; this occurs in separation of the upper epiphysis, and in high transverse fractures of the surgical neck. It will be evident that if union takes place with the upper fragment definitely abducted and the lower fragment in the position of adduction against the side of the body, abduction of the arm as a whole will afterwards be impossible at the shoulder-joint. There are two possible ways of obviating this form of vicious union: an operation may be performed, and the ends of the bone brought together and held there by plates, wires, or pins; or, if under an anæsthetic the lower fragment can be brought up to the upper one, the broken limb may be treated in the abducted position; (2) The shoulder-joint and the surrounding muscles may be matted by adhesions. This is apt to occur in all fractures at the upper end of the humerus as the result of prolonged immobilization, and is the commoner cause of functional disability. Fortunately it is also the cause more easily obviated, as adhesions are prevented by the employment of massage and movement. Where the muscles can be kept functionally active and the joint free from adhesions by this treatment, good functional results will be obtained, even although there may be considerable over-riding of the broken ends, or even if some angular deformity persists.

In the latter case, an increased mobility of the scapula will compensate for the restricted movements at the shoulder.

The injury may be (a) *Of the Anatomical Neck*; (b) *Of the Greater Tuberosity*; (c) *Of the Surgical Neck*; (d) *Separation of the Epiphysis*.

a. *Fracture of the Anatomical Neck*.—This is usually caused by direct violence, as in a fall upon the shoulder, and is often accompanied by comminution of the tuberosities. Should the upper fragment be separated from the rest of the bone, non-union is likely to occur and operation will be therefore indicated; but if there be impaction, union will probably take place.

TREATMENT.—Massage should be begun at once (see general instructions), and should be continued daily for about a month. Passive movement of the shoulder should also be employed from the first, very cautiously of course to begin with, and gradually increased. Active movements of the shoulder may begin about the fourth day; at first only slight movements of abduction, then movements forwards and backwards, and last of all movements of rotation.

The only apparatus required is a simple sling to support the forearm, the hand being left free so that active movements of the wrist and fingers may be made from the first. For the first day or two, if there is much pain, the patient will be easier in bed with the arm bound to the side. After the pain and spasm have subsided, he can go about with the sling beneath the clothes until after the fourth day; the sling may then be worn outside the clothes. All movements are to be controlled by pain and fatigue. Union is generally complete in a month, but treatment should be kept up until the movements are quite free.

Where there are simultaneous fracture of the neck and dislocation of the head, a serious operation will probably be required.

b. *Fracture of the Greater Tuberosity*.—This may sometimes be recognized by the presence of crepitus and of increased breadth of the shoulder, while by a finger in the axilla the head of the bone can be felt to move with the lower end of the shaft. In doubtful cases an x-ray photograph should be taken.

The TREATMENT is much the same as for fracture of the anatomical neck, with this difference, that the massage must chiefly be applied to the supra- and infraspinatus and teres minor muscles at first, that movements of rotation must be carefully watched, and that at first the joint must be kept from the formation of adhesions chiefly by swinging movements, others being added by degrees. A sling is needed as for the fracture of the anatomical neck. An operation may sometimes be necessary should the separation of the fragments be considerable.

c. *Fracture of the Surgical Neck*.—This is caused most frequently by a fall upon the shoulder; sometimes by a fall upon the hand or elbow. The diagnosis is based upon the tilting outwards of the lower end of the humerus, the head of the bone being in position, and increased mobility with crepitus at the upper end of the bone. A general anæsthetic may be necessary to establish the diagnosis and allow the fracture to be set, should massage fail to ensure the necessary relaxation of spasm.

TREATMENT.—The upper fragment cannot be controlled by splints. Still in most cases the treatment which answers best is that recommended for fracture of the anatomical neck. Should the upper fragment be much tilted outwards, the lower fragment must if possible be brought to it by being placed in the position of abduction. Middeldorpf's abduction splint in the form of a triangle can easily be made of wood, perforated zinc, or tin. The base of the triangle rests against the patient's trunk, while the other sides of the triangle support the upper and forearms respectively. Should the abducted position fail to keep the ends in fair apposition, the question of operation must be considered.

The abduction splint may have to be employed for two or three weeks ; but during that time the shoulder should be massaged every few days, and movements of the elbow and fingers encouraged. On the removal of the splint, a cushion should be employed as in the next case. This in turn should be dispensed with as soon as possible, probably in a week or two.

In cases where the upper end is not much tilted outwards, but in which the lower fragment is drawn inwards by the muscles inserted into the bicipital groove, the broken ends can be kept in position by laying the arm upon a wedge-shaped cushion which has its apex in the axilla. This cushion may be conveniently formed of a piece of cardboard bent upon itself, filled up with cotton-wool, and padded on the outside. The arm is then laid upon this cushion and bandaged to the side. After four or five days the bandages are loosened, the parts massaged and gently moved, and the arm again fixed up as before. This massage and movement are repeated in a few days, and generally at the end of about ten or twelve days the cushion can be dispensed with and only a sling employed.

d. Separation of the Upper Epiphysis.—This injury occurs in persons under 20 years of age, usually from direct, but sometimes from indirect, violence ; in fact it is often the result of an injury which would have caused a dislocation of the shoulder in an older person.

The symptoms resemble those of subcoracoid dislocation as regards the axis of the humerus and the presence of a prominence under the coracoid process. If the swelling is not too great, however, the head of the bone may be recognized in the glenoid cavity.

TREATMENT.—Under a general anæsthetic an effort should be made to restore the separated parts. The head of the bone is steadied with the fingers of one hand, while the arm is drawn away from the body and gradually abducted to its extreme limit. When the displacement is reduced, the limb is fixed in the abducted position in a Middeldorpf's splint, or in a plaster-of-Paris case. In the latter case massage must be postponed, but this is of less importance in young persons. After two or three weeks the plaster-of-Paris case is removed, and the limb massaged and cautiously exercised (Whitman). If the separated portions of bone cannot be brought into line an operation will be indicated.

Fractures of the Shaft.—These are caused usually by direct violence, but sometimes by a fall upon the hand or wrist, or by a twist.

Diagnosis is generally easy on account of the deformity and increased mobility ; non-union is common, but this does not seem to be due, as was formerly supposed, to movement of the fracture during the course of treatment, but to interposition of soft parts, or to the imperfect blood-supply of the lower fragment owing to tearing of the nutrient artery.

TREATMENT.—It will be necessary to make sure that the musculospiral nerve has not been torn at the time of fracture, or nipped between the fragments when the bones were being set. If the nerve has been torn, the ends must be sutured at once by operation. After massage, the ends of the bone can generally be brought into apposition. Although some cases can be treated with a sling only, without splints, combined with massage and movement, it will generally be advisable to encircle the limb with well-padded supporting splints, one at the outer and back part of the arm with an excavation over the outer condyle, and another shorter splint for the front and inner side. These may be made of Gooch's splint, poroplastic felt, or pasteboard. They must be well padded, and fixed tight enough to prevent angular deformity, but not to interfere with the circulation of the limb. The arm should be kept in a sling. The fingers and wrist should be moved voluntarily from time to time by the patient, and

passive movement of the elbow and shoulder should be made at the massage sittings every few days. At first the support of the splints should be maintained during the passive movements. The splints may be required for about three weeks. Union generally takes place in about four weeks.

If signs of involvement of the musculospiral nerve should appear during the formation of the callus, time should be given for the callus to consolidate and contract. If the nerve seems to be permanently involved, an operation to free it will be necessary. Massage should not be applied to the seat of fracture in such a case, as the callus will be thereby increased.

Delayed Union.—Should union be delayed, the activity of the healing process may be hastened by the measures already indicated for that condition (*vide supra*).

Fractures near and into the Elbow-Joint.—(a) Transverse fracture at the olecranon and coronoid fossæ; (b) T-shaped fracture; (c) Separation of the epiphysis; (d) Fracture of either condyle; (e) Fracture of either epicondyle.

These fractures are often very complicated and difficult to diagnose. The swelling is often great, and one or more of the fragments may be very small. After the history has been obtained and the aspect of the limb and possible voluntary movements have been observed, the following method of examination will be found useful, even when the swelling is great. Begin by massaging above the elbow, and try to reduce the swelling round the joint as much as possible; then follow with the fingers the subcutaneous ridge of the ulna from the forearm to the olecranon process, and see if the olecranon is fixed or transversely movable. Then compare the relations of the condyles with the olecranon on the two sides of the body. Grasp the lower end of the humerus by the condyles, and see if it is continuous with the shaft or not by making a movement in the transverse direction. Take each condyle separately between the finger and thumb, and try to move it antero-posteriorly. The bony points, although obscured by the swelling, can generally be made out by steady pressure over the place where they should be. In children, a transverse fracture through the olecranon fossa often occurs, even though the epiphysis has not united. A general anæsthetic and x-ray photograph should be employed where there is any doubt as to the diagnosis.

TREATMENT.—If displacement be slight or absent, keep the arm in a sling, and treat by massage and movements only. If displacement be well marked, reduce (under an anæsthetic if necessary), and bandage the arm into a rectangular posterior gutter-splint of metal, poroplastic felt, or plaster. If displacement be very great, reduce as before, but fix the elbow in acute flexion. Many surgeons prefer acute flexion in all cases. A small pad is placed in the bend of the elbow, and a figure-of-eight bandage put round the joint. Operation will be necessary if the symptoms point to the involvement of the ulnar nerve, or if the fragments cannot be properly moulded into position and retained there.

Massage and movement are of especial value in all fractures into the elbow-joint. Unless there is great tendency to displacement of the fragments, this treatment should be carried out daily at first. In addition to the general indications already given, the following points should be attended to. While the effusion should be dispersed as soon as possible, care must be taken not to stimulate the formation of callus by massaging the seat of fracture itself, especially in young children. The broken bone must be steadied during massage, and especially during active and passive movements. The masseur must make sure that any movement that takes place does so at the joint and not at the seat of fracture. The amount of movement must be regulated by the pain. Where pain restricts movement, there will be no gain in forcing the movement, which only calls forth contraction of the antagonistic muscles.

Where displacement tends to recur, the splints may be left undisturbed for two or three days. After about a week, the tendency to displacement will be very slight. On the other hand, if displaced fragments have not been replaced for ten to fourteen days, it will be difficult to rectify the position, even under an anæsthetic. Improvement in range of movements sometimes goes on for many months after the fracture has united, the patient's own voluntary efforts being of much assistance.

FRACTURE OF THE OLECRANON.

This injury is generally caused by direct violence, sometimes by the action of the triceps. Diagnosis is generally easy by manipulation (see method of examining for fractures of the lower end of the humerus). The patient's power of extension should be tested when the forearm is allowed to hang vertically from the abducted upper arm, i.e., in extension against gravity.

TREATMENT.—Formerly an apparatus was applied to keep the elbow extended and to draw down the upper fragment of the olecranon. This method, however, Lucas-Championnière finds quite unnecessary if the massage and movement treatment be carried out. The only appliance required is a sling, in which the arm rests at first at an angle of 135° , i.e., midway between full extension and a right-angled position, while round the elbow a bandage may be lightly applied, partly to support the parts and partly to meet the patient's desire to have some form of apparatus.

For the first day or two the patient may be more comfortable in bed with the arm lying on a pillow in a semi-extended position. In a day or two he will be able to get up and go about with the arm in a sling. The massage should be carried out with the limb in the most comfortable position, which is generally that of slight flexion, the limb lying on a cushion. After the use of the stroking movements already described for soothing the muscles gentle passive movements may be made, and so long as they do not excite muscular spasm they will not lead to separation of the detached fragments. The massage sittings are repeated daily, but for several days passive movement only is allowed at the elbow; gentle active as well as passive movements of the wrist and fingers are encouraged.

As the tenderness subsides, the massage is applied more deeply round the elbow-joint, and the range of movement is extended. It should be remembered that active flexion and passive extension movements are least likely to do harm. Usually complete flexion is possible in about three weeks, but full extension is often delayed; sometimes it is never quite regained. For many weeks after the movements of the joint are free the patient must abstain from any violent muscular exercise, especially such as will bring the triceps into strong action, lest the uniting callus should be stretched or torn.

Professor Lucas-Championnière finds that operation is not required in fracture of the olecranon treated by his method, and this experience has been amply confirmed by others who have adopted the method.

FRACTURE OF THE BONES OF THE FOREARM.

Fracture of Ulna and Radius is caused most frequently by direct injury. Diagnosis is easy owing to the deformity and increased mobility.

TREATMENT.—The fracture, if below the middle of the arm, must be set after relaxation of the muscles by massage or by a general anæsthetic. During reduction the forearm should be held supine. Splints must be employed to prevent recurrence of deformity. They must be broader than the forearm, and rigid, so that the broken ends of the radius and ulna are not pressed together. Union of the bones to one another would prevent pronation and supination.

The most convenient material is Gooch's splinting, applied with the wood towards the limb, and the leather outside. The posterior splint should extend from the olecranon, and the anterior splint from the bend of the elbow, to the wrist. This will allow free movement of the fingers and slight movement of the wrist.

After the first soothing massage the splints may be left undisturbed for four or five days. They will then be taken down and the limb massaged while the bones are steadied by an assistant. Slight movements of the elbow are possible with the splints in position, and hence do not need to be carried out at the massage sitting. Pronation and supination must be passive only at first, but even these must be delayed until all muscular spasm has subsided and the parts are beginning to solidify. While the patient is going about, the limb is laid in a sling in the supine position as much as possible.

Fracture of the Ulna alone and Fracture of the Radius alone between the insertion of the Pronator Teres and Lower End of the Bone, are to be treated as for fracture of both bones.

Fracture of the Radius above the insertion of the Pronator Radii Teres, i.e., in the upper half of the bone, with or without simultaneous fracture of the ulna, is caused by direct violence. The importance of this fracture is that the upper fragment of the radius carries both supinator muscles—biceps and supinator brevis—while the lower fragment has both pronators. The upper fragment rotates on its own axis, and cannot be prevented from remaining in supination. The lower fragment can, however, be controlled. Hence it is necessary to maintain the forearm in the position of full supination and flexion for two or three weeks, the massage and movement being carried out in other ways as if both bones were broken below the middle. The position of full supination cannot be voluntarily maintained by the patient without mechanical aid. Besides lateral splints, therefore, as for fracture of both bones, an additional splint is necessary to keep up supination. An angular elbow splint bandaged to the forearm splints will serve the purpose, or a straight piece of Gooch's splint about three inches broad, laid across the angle formed by the upper arm and the forearm splints, and fixed there with a firm bandage.

Fracture at the Lower End of the Radius (Colles's Fracture).—So much has been written about this, the commonest fracture in the body, that there is no need to do more than dwell on the points which seem to be of most importance in regard to treatment.

Two unfortunate possible sequences of this accident have to be obviated as much as possible by the treatment. One is a deformity, which results if the fracture be not reduced. The other, and more important, is stiffness of the wrist and fingers which results from immobilization. There is no necessary connection between these two. Many unrecognized cases of Colles's fracture have left a perfectly good functional result along with great deformity, because the patient has kept on using the wrist, although no attempt had been made to reduce the deformity. On the other hand, cases of Colles's fracture with slight deformity have often become stiff because of prolonged immobility.

TREATMENT.—As soon as the fracture has been recognized, the displacement should be reduced. A few minutes' massage of the arm, above the fracture, is of service as a preliminary. An anæsthetic is generally necessary. The obstacle to reduction, however, being osseous rather than muscular, gas and ether, or ethyl chloride, may be employed. The best way to reduce is to grasp the hand firmly, and begin by over-extending the wrist, which should be steadied by an assistant; then try to separate the fragments, while keeping up this position. Next, the surgeon, while maintaining the strain, gradually and strongly flexes the wrist and simultaneously forces forward the lower fragments

with the thumb of the disengaged hand. It may be necessary to repeat this manœuvre once or twice before the osseous deformity is rectified or materially improved. Some deformity will remain, due to effusion in the soft parts, but will gradually disappear.

After reduction, the limb should again be massaged, and then the question of apparatus has to be considered. Deformity does not easily recur after reduction; hence some surgeons recommend that no splints be employed at all. There are, however, two reasons why a simple splint may often be advisable. If there is muscular spasm, a certain amount of deformity may be reproduced by the action of the muscles; while the tenderness of the wrist often makes it very painful for the patient to steady his wrist if it is allowed free play. In severe cases it is therefore better to lay the hand and forearm on a well-padded anterior splint reaching to the palm. To this the hand and forearm should be lightly bandaged, either with or without the additional support of a dorsal splint. Massage of the forearm and wrist should be performed, daily at first, on the general principles already laid down. After the first week the sittings may be less frequent.

Passive movements should at first be confined to the fingers. As the pain becomes less, the movements may extend to the wrist. Pain should be taken as the guide to the extent of the movements. Active movements of the fingers generally begin about the third day and should be followed by slight active movements of the wrist as soon as the pain permits. Pronation and supination come last of all.

In cases where the displacement is slight and the pain not great, after reduction the wrist should be supported with a strip of plaster or a bandage, and the forearm laid in a sling with the hand hanging over the edge.

INJURIES OF THE CARPAL BONES.

The two most common injuries of the carpal bones are fracture of the scaphoid, and anterior dislocation of the semilunar bone, either separately or combined.

The cause is usually a severe twist or strain, such as might have produced a sprain.

Simple Fracture of the Scaphoid Bone.—Diagnosed even without the *x* rays, from “(a) History of a fall on the extended hand; (b) Localized swelling in the radial half of the wrist-joint; (c) Acute tenderness in the anatomical snuff-box when the hand is abducted; (d) Limitation of extension by muscular spasm, the overcoming of which by force causes unbearable pain” (Codman and Chase).

TREATMENT.—Rest of hand on an anterior splint for three or four weeks, with massage and gentle movement. If there is no union in that time, none probably will take place at all, and the wrist may remain permanently impaired in function. In that case operation is indicated to remove the proximal portion of the broken bone. (See Codman and Chase, *Annals of Surgery*, vol. 41, for details of the operation, and for the diagnosis and treatment of dislocation of the semilunar bone).

FRACTURE OF A METACARPAL BONE.

The commonest fracture of a metacarpal bone is that of the base of the metacarpal bone of the thumb—“Bennett’s fracture.” It is caused by a blow in the long axis of the thumb (on the point), whereby the anterior portion of the surface which articulates with the trapezium is split off. A partial dislocation backwards results.

TREATMENT.—Extension; replace the metacarpal bone, and prevent it from passing backwards again by the pressure of a firm pad held in position with

a splint which reaches from the lower end of the radius to the end of the thumb. Several forms of splint have been recommended. The most useful is a piece of Gooch's splinting, a little wider than the thumb and of the requisite length.

Massage for a few days should be carried out, also passive and active movements while the proximal end of the bone is steadied by the grasp of a finger and thumb. Bennett advised the use of a splint for four weeks, but with massage and movement this time may be considerably diminished.

Fractures of one of the four Inner Metacarpal Bones.—This may be caused by direct violence. An important point in diagnosis is the shortening. The patient should be made to close both hands, and the level of the heads of the metacarpal bones should be compared on the two sides. In doubtful cases crepitus or abnormal mobility in the suspected bone may be looked for.

TREATMENT.—Bandage the forearm and hand to an anterior splint, with a good pad for the palm, or bandage the closed fist with a pad in the palm, and support the forearm in a sling. Massage the hand and forearm, at first daily ; after the first week, at intervals of a few days. Passive movements of the fingers should be employed from the first. In a few days encourage active movements. Union takes place in about three weeks.

FRACTURES OF THE RIBS.

Treated by the usual methods of strapping and firm bandage.

FRACTURES OF THE PELVIS.

The general principles which have been laid down for the treatment of fractures elsewhere should be applied to the pelvis—i.e., massage to the neighbourhood of the fracture, gentle passive movements to prevent stiffness of the hip-joint, and active movements cautiously increased.

The patient should be in bed for from six to eight weeks ; a bandage round the pelvis will be found a comfort for the first two or three weeks.

FRACTURES OF THE BONES OF THE LOWER LIMB.

Fractures of the Neck of the Femur.—A good deal of the difficulty in diagnosing the intra- from the extra-capsular fractures may be traced to an imperfect understanding of what it is that really makes the difference between the two forms of fracture. The mechanism which produces it is different in each case. The *intra-capsular* fracture is caused by a twist or strain which acts transversely or obliquely to the long axis of the neck. The bone is not likely to give way from this form of injury unless it has been previously weakened by disease or senile atrophy. The *extra-capsular* fracture results from violence applied to the great trochanter—almost without exception from a fall upon it—and which therefore acts more or less directly along the axis of the neck. Aged and fragile persons, just as much as those who are younger, will suffer from this form of fracture, and not from the intra-capsular form, if they happen to fall upon the great trochanter. The *intra-capsular* fracture is a mere transverse break of the neck of the bone ; it is seldom impacted, but when this does occur, the lower fragment—neck—is driven into the upper—head. The *extra-capsular* fracture is really a break between the neck and the great trochanter. It is always impacted—at first, at least—and, as the result of this impaction, in severe cases the trochanter is split up into several fragments.

The history of the nature of the accident is therefore of great importance in diagnosis. In extra-capsular fracture, the history of a fall upon the trochanter, and the presence of thickening when it is grasped between the finger and the thumb, are generally sufficient to establish the diagnosis. *Raising of the trochanter*

accompanies either form, although in the intra-capsular form, until the ligament softens, the raising may be very slight. *Crepitus* should not be looked for, lest impaction should be undone in the one case, or some reflected portions of the capsule which carried blood-vessels should be torn in the other. *Eversion* occurs in both forms of fracture, as well as in a mere bruise of the hip.

In intra-capsular fracture there will be the history of a twist or jerk of the neck of the bone, often the sound of something giving way; then sudden inability to use the limb, and the patient falls to the ground. The diagnosis is often best arrived at by exclusion.

Extra-capsular Fracture.—This is much the commoner form of the two. Bony union with eversion and some shortening takes place almost invariably; but the patient is crippled, not from this, but from the ankylosis of the hip-joint which results from the period of immobilization which is usually enforced.

In the comparatively rare cases in which the fracture occurs in men who are still able for active work, much benefit results from undoing the impaction (if considerable) under an anæsthetic. The limb, having been wrenched into the abducted position, is kept there. Massage is applied to joint and muscles, and gentle passive movement begun in about fourteen days.

Lucas-Championnière trusts to early movement in these cases more than to massage. He fears that massage over the large veins in old people might set free a clot, and so he confines the massage chiefly to the posterior aspect of the hip. If there is much muscular spasm, and especially if the impaction has become lessened, extension of the limb with weight and pulley is advisable, but it need not be continued for more than ten to fourteen days. No splint should be used, only sand-bags to steady the limb. Massage of the posterior and outer aspects of the hip may be employed daily or every few days. After a period varying from five to fifteen days, the patient should get out of bed and should move about a little on crutches with an assistant on each side, at first at least. The sound foot should be raised with a high heel. Gentle swinging movements of the thigh should be encouraged, the range being increased as strength returns. Active movements of the foot, ankle, and knee should be made after the first day or two. The patient cannot bear weight upon the injured limb until eight to ten weeks have elapsed.

Intra-capsular Fracture.—Professor Lucas-Championnière does not discriminate this from the extra-capsular form in his account of the treatment. In view of the progressive shortening which takes place after the capsular ligament has given way, extension with weight and pulley is advisable for three or four weeks, if the patient's health permits recumbency for so long. A Thomas's hip-splint should be worn in bed for about the same time, and the limb should be steadied with sand-bags. Massage as indicated already for the extra-capsular form of fracture should be applied for a few days at least. The patient may be raised in bed almost from the first, although the bed will be tilted up at the foot in order to provide counter-extension. The stages in the progress should be similar to those of the extra-capsular form, but from two to four weeks later.

If there is no union at the end of ten or twelve weeks, the patient must depend on bearing his weight upon ligaments, which will grow stronger as time elapses. A firm belt round the pelvis, extending below the trochanters, will be helpful.

Fracture of the Shaft just below the Lesser Trochanter.—This generally occurs in old people as the result of a twist, and the line of fracture is often oblique. Fortunately the injury is a rare one, for it is probably without exception the most difficult fracture in the body to treat satisfactorily. The upper fragment, short and sharp-pointed, is forced forward by the powerful psoas and iliacus muscles, while the lower fragment is drawn up behind it by the

hamstrings and adductors. An immediate operation to wire the ends together would be the best treatment if the circumstances permitted.

As regards apparatus, a double inclined plane is advisable to keep the hip and knee-joints flexed, while traction with weight and pulley is applied to the thigh. Sand-bags may be used to steady the limb. The surgeon will be fortunate if he can keep the ends of the bones in apposition, even with considerable over-riding. The muscles for which the soothing effect of massage is most needed (psosas and iliacus) are out of reach.

Fracture of the Shaft of the Femur is caused both by direct and indirect violence. Diagnosis is generally easy from the distortion and unnatural mobility. The patient is not able to lift his leg on account of the pain so produced, which is due to the distortion at the seat of fracture.

TREATMENT.—The limb should be steadied and extended by an assistant, while massage is applied to the upper part of the thigh. If the broken ends do not come into good apposition a general anæsthetic should be administered, but while the patient is going under, the seat of fracture should be supported with splints. Extension plasters should be applied from the lower part of the thigh to the ankle. The amount of weight will depend upon the muscular development of the individual, and will vary from about 9 to about 30 lbs.

The shaft of the bone must be supported by local splints. The most convenient material for this is Gooch's splint, cut in the form of two or more pieces, so as to surround the thigh. Sand-bags should be used to steady the limb and to prevent rotation outward of the lower fragments, but in the case of unruly or restless patients the addition of a long splint is advisable.

After three or four days the splint should be taken down, and while the limb is steadied and extended by an assistant, the thigh should be massaged and the knee-joint firmly flexed. Massage should be repeated every three or four days, or oftener if there is much pain. One great cause of after-trouble is stiffness of the knee resulting from adhesions between the quadriceps extensor and the seat of fracture. For this reason, passive movement of the knee is begun early, and after about fourteen days the patient may move his knee voluntarily from time to time during the day.

Dagron finds that union takes place in about eight weeks. When the patient begins to use the limb, the thigh should be supported by splints, the knee and hip-joint being free. A slight amount of weight put upon the bone hastens solidification, but the strain should be cautiously increased. Owing to the risk of an apparently firm callus yielding under the patient's weight, there is a great advantage in the use of a Thomas's caliper knee splint when the patient first begins to go about. Failing that, crutches should be used. Under the massage treatment the patient can frequently lift his extended leg off the bed in about three weeks, but he is seldom able to be out of bed under eight weeks. As the patient gains in confidence he may dispense with one, then both crutches, and afterwards use only a stick, until he can walk unaided.

Fracture of the Femur in Children.—It is noteworthy that in children fractures of the femur are more frequently met with than fractures of the leg-bones; they are usually more or less transverse. Children are not easily kept quiet or dry, and therefore treatment is complicated by two conditions, unrest and moisture. We meet these difficulties by using the double long splint or vertical extension. The double long splint is, moreover, well suited for restless adults. It may be used with or without extension.

For fractured femur in infants Robert Jones recommends a Thomas's knee splint applied as follows:—

“Extension plasters are applied to the leg below the fracture, and the limb is passed through the ring, which encircles the thigh at the groin, and which is

padded over with felt, leather, and impervious oilskin. The thigh is pulled, and the extension is maintained by the plasters, which are affixed to the lower end of the splint. A bandage is placed round the limb, and no further treatment is needed than now and again to extend the limb by pulling at the plasters. The little patient can be carried, nursed, left to play on the floor, and no displacement of fragments is possible. It can be applied easily in five minutes, whether the child struggles or not, and an anæsthetic is never needed.

Fracture of the Femur above the Condyles.—The diagnosis may be made by the unnatural lateral mobility and crepitus a little above the knee on attempted movement. Distortion may be masked by the swelling at the knee. A general anæsthetic should be administered, and if the position of the fragments is doubtful an x-ray photograph should be taken.

TREATMENT.—The special difficulty in treatment in this fracture is due to the backward displacement of the lower fragment by the gastrocnemius muscle; but the hamstrings also tend to cause over-riding. Fix thigh, knee, and leg in the flexed position upon a MacIntyre or similar splint. Should this method fail to ensure a good position, the tendo Achillis should be divided and the limb treated in the straight position. Extension of the leg by weight and pulley would also be useful. Massage of the muscles of the thigh and of the knee-joint should be carried out daily. Passive movement must be reserved until pain and tendency to spasm have passed off. In about a week it may be cautiously begun, while the seat of fracture is steadied, care being taken that any movement produced takes place at the joint and not at the seat of fracture.

Fracture of the Femur into the Knee-Joint.—This is the result of direct injury; either condyle may be broken off, or the fracture may be T-shaped. The diagnosis is as in the last case.

TREATMENT.—Careful massage of the thigh and knee-joint; then the joint should be steadied with splints in a slightly flexed position, while extension with weight and pulley overcomes the disturbing influence of the muscles which act upon the knee-joint. Passive and active movements must be used as soon as the pain and muscular spasm have sufficiently subsided, probably about the fourth or fifth day. Afterwards the sittings for massage and movement may be continued, at first daily, and then at longer intervals, the range of movements being gradually increased. Traction should be discarded as soon as the fragments will remain in position without it, generally in from fourteen to twenty-one days. An operation may be called for when the fragments cannot be properly reduced by manipulation.

Fracture of the Patella.—Caused most frequently by muscular action; sometimes by direct violence. The *diagnosis* is made from the history, from the great swelling without adequate cause other than that of a fracture, from the patient's inability to lift the leg from the bed, and from the presence of two separate parts of the patella—probably without crepitus, as blood-clot generally covers the broken surfaces.

TREATMENT.—The most rapid and the most complete return to functional usefulness is given by immediate operation, clearing out clots from the joint, and wiring the broken surfaces of bone together. On the other hand, there is probably no fracture in the body in which the risks to the patient's life and limb are greater than in that of the patella if the wound should become septic. For this reason the majority of surgeons prefer non-operative measures, and those who do operate upon vigorous patients, decline to do so when the patient is old or unhealthy. Fibrous union, which is all that can be counted upon without operation, gives in most cases a good useful limb, and a fibrous union about one and a half or two inches, or even longer, is preferred by some to a shorter, or a partially bony, union, which is apt to give way. The most serious obstacles to

functional usefulness are adhesions in the joint and between the upper fragment and the surrounding parts. These can be obviated to a large extent by massage and early movement. Wharton Hood, after three or four days' massage, applied a strip of adhesive plaster three inches wide round the lower third of the thigh, and made his patient get up and walk about with the aid of a stick, renewing the plaster as it became loose. Tilanus advises the patient to walk in from six to twelve days, and Lucas-Championnière agrees with him. All advocates of the massage and movement method unite in condemning the older appliances by means of which the joint was rigidly fixed in an extended position for several weeks, and they have abandoned the various devices which were intended to bring the broken surfaces together.

For the first few days the limb should be steadied in a splint with the knee in the most comfortable position, probably that of slight flexion in a MacIntyre splint, or a gutter splint made of Gooch's splinting or pasteboard. The splint may be steadied with sand-bags. When pain has subsided, the limb may be left free in the bed. From the first, the muscles of the thigh and knee should be well massaged daily, to reduce the swelling and subdue spasm. When the massage is finished, the knee should be gently flexed. Lucas-Championnière finds that a very slight range of movement suffices to keep the joint supple, and he thinks it an advantage, therefore, to allow the leg to lie free in bed as soon as the patient can comfortably do without support. While the foot rests on the bed, the patient may flex the thigh, and this flexes the knee. Dagron advises that semi-flexion should not be exceeded before the fifteenth day. The upper fragment should be steadied by the surgeon's hand, while passive movements are to be carried out, and the range of movement should be cautiously increased. As soon as possible the patient should be encouraged to walk on his leg. A light posterior splint to support the joint in the efforts to walk would provide security against the knee giving way. Although the range of passive movements can be extended by degrees, the weight of the patient's body must not be thrown upon the uniting structures for several months. Patients to whom it is important for any reason to be out of bed soon, will be able to walk about at once if fitted with a Thomas's caliper knee splint.

Fracture of both Bones of the Leg.—If the displacement cannot be reduced after the muscles have been soothed by massage, the patient should be anæsthetized in order to facilitate free manipulation of the broken ends of bone while the muscles are relaxed. Only in a small proportion of cases will operation be required on account of the entanglement of soft parts, or of great displacement of the broken ends, not otherwise remediable. When mere over-riding from obliquity in the line of fracture is the cause of marked deformity or endangers the skin, extension upon the foot by weight and pulley for a week or two should be employed.

At first, while the muscles are inclined to contract in spasm, the patient will be relieved if the foot, as well as the seat of fracture, be supported. After a few days there will be an advantage in allowing free play to the ankle, so that the patient may spontaneously move the foot from time to time between the surgeon's application of massage and movement. Hence a supporting splint which can be employed with or without a support to the foot will be best, but one with a fixed foot-piece which can be easily taken down for massage will serve the purpose very well. In about three weeks there is generally so little tendency to displacement that the limb may be allowed to lie in bed unsupported, or steadied only by lateral sand-bags. At this stage the patient may be allowed out, going about on crutches with lateral pasteboard or poroplastic splints which do not confine the knee or ankle-joints. In favourable cases weight can be borne on the fractured leg in about six weeks.

Pott's Fracture of the Fibula.—

TREATMENT.—Where there is not much displacement, the limb should be well massaged, especially along the outside, to soothe the spasm of the peronei muscles. The patient should then by voluntary effort try to assist the surgeon in restoring the foot in position (see p. 391). The limb should then be again massaged and steadied with a Dupuytren's or a "box" splint, or any of the forms of leg splint which have a foot-piece. The splint should be removed for massage and movement daily, and at each sitting the foot should be brought nearer to its proper position, if it has not retained its position since it was replaced on the previous day. If the restoration is not complete on the first day, it will be better the second, and so on until it remains in position without difficulty. After about a week to ten days, the tendency to displacement will have passed off, and the patient will be able to move the ankle in all directions, with only a steadying hand placed over the malleoli. In from fourteen to eighteen days, if there is continued progress, the patient may be allowed to rest in bed with his foot tied in a pillow or quite free, and in about three weeks a supporting splint of plaster of Paris, poroplastic materia, or paste-board should be bandaged to the outside (or on both sides if required), and the patient should walk about with the aid of a stick. The surgeon must watch the effect of the patient bearing weight on the injured foot. If there is outward displacement, the treatment in bed must be continued, and the parts allowed to become more secure in their normal position before walking is attempted.

In cases in which the displacement outwards and backwards is very marked, the ligaments are more extensively torn, and the muscular spasm is sometimes so great as to endanger the vitality of the skin over the inner malleolus. If careful massage, aided by the patient as before, does not suffice to obtain a marked improvement in position, a general anæsthetic should be given and the deformity reduced. The leg should be fixed in a Dupuytren's splint and laid on its outside with the knee flexed; or preferably the foot and leg may be laid on an outside straight or gutter splint (Cline's), with thick padding under the outside of the foot, and steadied there with a bandage. Massage should be performed daily, and after the muscles have been soothed the foot should be guided into position until it can be inverted by the patient's own efforts, supplemented by gentle traction by the surgeon. The subsequent treatment is similar to that described for cases with slight displacement, with the difference that the stages are more prolonged. Since the tendency to outward displacement remains after six or seven weeks of treatment, the patient when first beginning to walk should have the inside of the boot raised so as to throw the foot on its outer edge, while the foot is strapped to a steel carried along the inner side of the leg and fixed into the heel. The steel must be bowed opposite the inner malleolus if the skin there is tender. To the steel are fixed straps which draw the foot and ankle inwards when the patient bears weight on the foot (Jones). Sometimes the posterior tip of the lower articular surface of the tibia is broken off. The foot will then slip backwards very easily. Extension of the foot with a weight should be tried, and failing success with that, an operation will have to be considered.

Fractures of the Tarsal Bones.—The bones frequently fractured are the astragalus and the os calcis. The causes are falls on the heel, crushes, and twists. Diagnosis will be made from the history of the accident, from distortion of the foot, and from crepitus elicited by careful manipulation. An *x*-ray photograph is important.

TREATMENT.—Rest in bed, massage, and movements carried out on general principles. An operation will be advisable when, for instance, the bony portion where the tendo Achillis is inserted is torn off, or when the broken astragalus becomes displaced and hinders the proper use of the joint.

Fractures of the Metatarsal Bones occur as the result of direct injury, or from marching, or dancing. Diagnosis is based on the history, the presence of swelling, pain, tenderness, and crepitus.

TREATMENT.—Rest and massage.

Charles W. Cathcart.

FRAMBÆSIA TROPICA.—(See YAWS.)

FRECKLES.—As freckles give rise to no symptoms, they call for treatment only when they are very numerous on exposed parts, and give rise to disfigurement. On the face they may be prevented by the wearing of a brown or red veil, as they are produced by the actinic, and not by the heat, rays of the sun.

There are numerous methods for removing them, and the object of most of these is exfoliation of the epithelium containing the pigment. By far the best agent is corrosive sublimate in one or other form. Other remedies are certain acids—e.g., nitric, hydrochloric, or lactic—caustic alkalies, borax, bismuth compounds, and peroxide of hydrogen. A simple application is 1 per cent solution of HgCl_2 in alcohol, applied daily until irritation is produced. Unna recommends the application of a peeling paste of resorcin (50 per cent in zinc paste). This necessitates the patient's staying in the house. He also recommends the following ointment :—

R. Unguenti Zinci	30 parts	Adipis Lanæ	5 parts
Bismuthi Subnitratis	1 part	Hydrargyri Ammoniat	2·5 parts
Olei Olivæ	5 parts	Sol. Hydrogenii Peroxidi 10%	20 parts

The following is recommended in Vienna :—

R. Hydrargyri Ammoniat	Barii Sulphatis	āā 1 part
Bismuthi Subnitratis	Vaselin	30 parts

FRONTAL SINUSITIS.—(See NOSE, ACCESSORY SINUSES OF.)

GALL-BLADDER, INFLAMMATION OF.—(See CHOLECYSTITIS.)

GALL-STONES (Medical Treatment).—Treatment based on the possibility that gall-stones may be dissolved out of the body by various solvents is sometimes recommended; but solvents of a sufficient strength cannot be administered without seriously injuring the mucous membrane of the alimentary tract. In weak solutions none of the so-called saline cholagogues have any solvent effect. Dr. Brockbank found that a 1 per cent solution of salicylate, phosphate, benzoate, bicarbonate, or sulphate of soda failed to produce any loss of weight in biliary calculi allowed to stand in them for fourteen days.

Olive oil has been recommended as a solvent for gall-stones, and experiment shows that if a gall-stone be placed in olive oil it gradually loses a large percentage of its weight, and may break up into small pieces. The same result is produced by oleic acid and by animal soaps. Doubts, however, are expressed as to whether administration of olive oil can have any influence on gall-stones in the biliary passages, as the oil as such cannot enter into these tracts. But, as Brockbank points out, oils and fats become disintegrated in the alimentary canal, and pass into the blood as an unchangeable fat, a fatty acid, and as soap, all three of which dissolve cholesterol readily and break up a gall-stone. It is possible, then, that the substances resulting from the digestion of the oil so reduce or soften gall-stones in the biliary channels that they pass into the intestine, or even short of that, may become less angular and produce less discomfort.

Certainly, many authors have found that administration of olive oil gives more

relief than any other medicinal measures to patients suffering from symptoms of cholelithiasis. The oil should be given in 3- or 4-oz. doses in the early morning, or at any rate on an empty stomach. Oleate of soda is sometimes given instead of olive oil.

Massage was recommended by the late Dr. G. Harley, with the object of expelling gall-stones from the gall-bladder, but seems likely to produce injury to the biliary passages, and is not to be recommended.

Turpentine has been stated to bring about expulsion of calculi, but Prevost's and Benet's experiments show that it can only enter the bile in very small amount, and though turpentine does bring about expulsion of some renal calculi, the author has not found any such result in cases of biliary calculi.

Although gall-stones cannot be dissolved in the biliary passages, treatment may lessen the formation of fresh ones and the enlargement of existing calculi.

Various diets are recommended. All food, and more especially protein food, is found to increase the secretion of bile acids which dissolve cholesterin; hence free meat-eating has been advised, but this tends to digestive disturbances, which should be avoided, and a mixed meal produces the best effect on account of the active chymification to which it gives rise (Ritter). Fatty food is often ill digested (though olive oil may be well borne), and rich and highly spiced food is to be avoided; but cholelithiasis does not call for any further restriction in diet (Naunyn), and the best diet for a patient with tendency to gall-stones is plain roast and boiled, without excess of meat. Free drinking of liquid is to be encouraged, though water is not a cholagogue; alcohol is unnecessary or injurious, but Vichy and Seltzer water are useful.

Exercise—walking, gymnastics, and swimming—are very necessary; gentle abdominal massage is recommended. No tight corsets or other tight clothing should be worn.

Constipation is to be met by occasional 1-gr. doses of calomel, and if aperients are needed more often, phosphate or sulphate of soda or Carlsbad salts.

Among cholagogues there is none comparable in effect with that of a full meal (Naunyn), but salicylate of soda increases and renders the bile more liquid, and the bile acids are also good cholagogues.

There is a very general experience in favour of warm sodium waters such as Vichy (temp. 110° F.), Carlsbad (158° F.), Neuenahr (95° F.); and Naunyn testifies to the favourable results of Carlsbad treatment in long-standing and unfavourable cases of cholelithiasis.

When biliary calculi pass into the bile-ducts and jaundice results, or when they pass into the cystic duct without the production of jaundice, biliary colic may arise. This is of every degree of severity, the exhaustion and collapse becoming dangerous in the worst cases. Unless there be any contra-indication, a hypodermic injection of morphia of $\frac{1}{4}$ gr. should be given at once. There seems no reason why this, the most effective measure, should be kept as a last resort, but a hot bath, hot fomentations with or without belladonna, and chloroform inhalation are also recommended. The drinking of hot weak solutions of bicarbonate of soda was recommended by Prout to relieve the retching on an empty stomach.

In many cases stone in the gall-bladder is accompanied by symptoms so slight as to be neglected or ignored, and the question of operation will not arise, though even in these cases serious results may ultimately ensue. But where the symptoms render it fairly certain that gall-stones are present in the biliary canals, the question of operation arises. No doubt the symptoms may eventually entirely subside, after or without repeated attacks of colic, the stone passing onwards or subsiding into quiescence in the gall-bladder. But on the other hand, the dangers of gall-stones are many: abscess, sloughing, or gangrene

of gall-bladder, ulceration through the bile-ducts, infective or suppurative cholangitis, and intestinal obstruction being among the number. And when a gall-stone remains impacted in the bile-duct, persistent jaundice adds a danger which cannot be ignored.

Stone in the cystic duct produces no jaundice ; nevertheless it may lead to great distention of the gall-bladder and sometimes to its sloughing or abscess. Calculi in any part of the biliary passages, gall-bladder, or ducts are liable to lead to development of cancer. Naunyn states that cancer of the gall-bladder never occurs without calculi ; the same appears true of cancer of the bile-ducts, and cancer of the pancreas is frequently associated with biliary calculi. This is a danger increasing with the duration of the stay of the calculus in the biliary canals ; and in the author's opinion, calculi should be removed by operation in all cases in which the general condition of the patient allows.

Sidney Phillips.

Surgical Treatment.—When the presence of gall-stones has been diagnosed, the question at once arises whether the case is suitable for palliative treatment or whether operation should be advised. The following are the main points to be considered :—

1. Palliative treatment gives relief in mild cases, but can never cure the patient ; there is no drug known which can cause any absorption of gall-stones ; some of the stones may pass down the ducts into the intestine, but most will remain in the gall-bladder.

2. Whilst stones are in the gall-bladder, there is always the risk of their setting up an acute inflammatory condition, or of one becoming impacted in the common duct ; operation will then have to be undertaken under very serious conditions, involving grave risk ; on the other hand, the operation for stones confined to the gall-bladder and the cystic duct is one of the simplest and safest in abdominal surgery.

3. It has been clearly proved that there is a very close relationship between gall-stones and carcinoma of the gall-bladder and ducts, and further, it seems that malignant disease arises far more frequently from stones which have caused trouble during life than from latent stones. Dr. Rolleston states that carcinoma of the gall-bladder and ducts occurs in from 4 to 14 per cent of all persons with gall-stones. This is a strong argument in favour of operation in the earlier stages.

4. The age and general condition of the patient must be considered. It may be laid down as an absolute rule that in all young healthy subjects with definite signs of gall-stone disease operation should be urged ; but many of the subjects are elderly and feeble, and in some of these operation should not be advised unless the indications are urgent.

Palliative Treatment is justifiable in the following cases : (1) Those in which there are mild attacks, the patient being quite free from symptoms in the intervals, and without tenderness or swelling in the gall-bladder region ; (2) Cases of patients who are old, feeble, and obviously in bad general condition ; operation would then not be advised unless the local condition were seriously threatening life ; (3) Palliative treatment is indicated in the early stage of impaction of the stone in the cystic or common duct, unless there are also signs of local peritonitis or septic infection ; some of these impacted stones pass into the bowel after a few days' palliative treatment, and then, if an operation upon the gall-bladder or duct is thought advisable, it can be performed in favourable circumstances later. Jaundice due to stone impaction, and lasting more than three weeks, is unlikely to be relieved by medical treatment ; in a few cases the stone ultimately passes into the bowel, and this involves a serious

and often long illness, which could be avoided by operation at a much smaller risk.

Operative Treatment is indicated in the following circumstances : (1) Attacks of marked biliary colic recurring in spite of medical treatment : there are many women who suffer for years from the pains and discomforts of gall-stones who would at once be relieved by operation ; medicine is usually powerless to check recurrence of the attacks in these cases, whilst complete relief is the rule after operation, recurrence being very exceptional ; (2) Peritonitis is always a clear indication for operation ; mild localized peritonitis may often be allowed to subside under palliative treatment, but when this has occurred, operation should be insisted upon ; any more severe degree of peritonitis demands immediate laparotomy ; (3) Septic infection involving the gall-bladder or ducts, showing itself by fever, rigors, etc. ; (4) Definite and persistent swelling of or around the gall-bladder ; (5) Jaundice of more than three weeks' duration.

OPERATIONS.—

Cholecystostomy is the operation most often performed for gall-stone disease. The gall-bladder is exposed by an incision through the outer part of the rectus muscle ; it is then incised, the stones are removed, and a rubber tube about half an inch in diameter and with no lateral perforations is inserted into the opening in the gall-bladder and fastened by means of two purse-string sutures of catgut. The gall-bladder is then allowed to drop back into position, and the abdominal wall is closed around the tube. The drainage tube should be long enough to lead into a receptacle by the side of the patient, in which the bile is received. The cystic and common bile-ducts must always be carefully examined, for it is essential that they should be clear. Free drainage usually occurs for from two to four weeks, and the wound then closes, provided of course that the ducts are patent.

Cholecystotomy is the operation in which the opening made in the gall-bladder is closed by suture after removal of the stones. This operation is seldom practised, for the risks of leakage are great, and moreover it is recognized that drainage of the gall-bladder is essential for the cure of the chronic inflammation which is almost always found in association with gall-stones.

Cholecystectomy is undoubtedly the best operation for certain cases of gall-stone disease in which there is no doubt that the common duct is patent, and it is probable that in the future it will be performed more frequently than is at present the custom. In this operation the gall-bladder with its stones is completely removed, and the cystic duct is closed by suture and a peritoneal flap. The operation is at least as safe as cholecystostomy ; it is a radical measure, corresponding closely to the removal of the diseased appendix ; recurrence of stones and the possibility of malignant disease starting in the damaged gall-bladder are prevented ; the convalescence is shorter. The loss of the gall-bladder causes no inconvenience whatever to the patient ; digestion is in no way affected.

Choledochotomy is the operation by which stones impacted in the common bile-duct are removed by incision of the duct ; if, however, the stone is situated in the terminal portion of the duct, and it is impossible to manipulate it into the upper part, the stone is best removed by incision through the anterior wall of the duodenum.

T. Crisp English.

GANGLION.—The following methods of treatment may be adopted :—

1. *Counter-irritation with Pressure.*—The swelling should be painted with tinct. iodi fort. and firmly bandaged or strapped. In a certain number of cases this will be successful.

2. *Puncture.*—A tenotome is inserted beneath the skin, with due regard to

the anatomy of the part, and the swelling is freely incised, a valvular opening being made. Pressure is then exerted over the swelling, so that its contents are extruded. A collodion dressing is applied with firm pressure, so that the walls of the cavity are brought into apposition. It is better to allow the gelatinous contents of the ganglion to escape externally rather than into the cellular tissues, and the whole proceeding must be conducted under the most careful asepsis, or very serious, even disastrous, results may occur.

3. *Excision*.—When a ganglion resists the above methods of treatment, or when the surgeon and patient both desire a speedy cure, the ganglion may be exposed by a free incision and dissected out. The tendon sheath, or sometimes a joint cavity, may be opened, but if absolute asepsis is maintained there is no danger. Subsequently, early movement of the part must be undertaken to prevent the tendon from becoming fixed by adhesions. (See also TENDONS AND TENDON-SHEATHS, INFLAMMATION OF.)

W. H. Clayton-Greene.

GANGRENE.—The various causes of gangrene are not considered in this article, but mention must be made of the close association of diabetes and Bright's disease with this condition.

TREATMENT.—There are two main forms of gangrene: *dry* and *moist*.

In Dry Gangrene the arterial flow is checked, but the return of blood and fluids along the veins and lymphatics is not interfered with. As the result of this the tissues die and shrivel up, undergoing a process of mummification without the occurrence of any septic changes. If untreated, in the course of time the dead material is cast off by the action of the granulation tissue which springs from the living parts at the *line of demarcation* between the living and the dead. This line of demarcation is not immediately defined, and even when amputation is considered necessary, it is advisable to wait until this limitation is established before deciding on the actual operation which is to be performed.

As a rule it may be said that the treatment of dry gangrene is amputation—in such a situation as will ensure the flaps being nourished adequately; and since the blood-supply of a limb is richest in anastomosis in the neighbourhood of the joints, these localities are usually selected.

In deciding on the particular form of amputation, preference should be given to that variety in which the flaps, while adequate for covering, are short and vascular, so that as little strain as possible will be thrown upon the failing circulation of the part.

In certain cases where constitutional disease is advanced, or where the arterial degeneration is very marked, no radical treatment should be attempted. The gangrenous parts should be cleansed and dressed antiseptically, and the natural separation assisted by the division of tendons and other resistant structures. Such treatment is not satisfactory, while the process of separation is often productive of very great pain.

In some cases of diabetic gangrene, excellent results have been obtained by amputation, and the amount of sugar in the urine has been found to diminish after the removal of a gangrenous extremity.

In Moist Gangrene, on the other hand, we meet with a condition where the return of the fluids, blood, and lymph has been prevented. In this variety the tissues remain sodden with their contained fluids, and form a suitable medium for the development of micro-organisms. Moist gangrene is not necessarily septic, but the conditions are so favourable to micro-organisms that septic changes are almost inevitable. In cases where this variety of gangrene is feared—that is, where there has been interference with the venous return from a limb—every care should be taken to keep the parts aseptic, and a thorough toilet of the skin should be undertaken. The hairs should be shaved

off, the limb should be well washed with ether, soap, turpentine, and spirit, special attention being directed to the limb folds and the regions of the nails, and a large antiseptic dressing should be applied. If, owing to these precautions, no septic complications arise, it is right to wait until a line of demarcation is defined before proceeding to amputation; but should the appearance of the limb and the condition of the patient suggest a septic state, no time must be lost in performing an amputation well above the gangrenous area.

The treatment of *senile* gangrene consists in practising amputation at a convenient spot as soon as the line of demarcation has declared itself, or in waiting for the natural process of separation of the dead from the living tissues, assisting it occasionally by division of a resistant structure. This form of gangrene is generally due to arterial sclerosis with blocking of the main vessel, and it is advisable, before deciding on the particular operation to be performed, to ascertain whether the main vessel of the limb is obstructed for some distance above the gangrenous area. Whenever amputation is attempted, the incision should pass through healthy tissue well above the disease, and short vascular flaps should be formed. In senile gangrene of the foot, it is better to amputate through the lower third of the thigh than to attempt any operation below the knee.

Anastomosis of the artery and vein has been tried in some cases of threatening dry gangrene. One or two successful cases have been published, but the writer does not think the method is to be recommended generally.

Raynaud's Disease.—For the milder forms of this disease in which necrosis has not occurred, the best forms of treatment are massage, electricity, and hydrotherapy; these are persisted in with the hope that the sluggish circulation may be re-established.

Barlow recommends the following procedure: "Immerse the extremity in a large basin containing salt and tepid water; one pole of a constant current battery is placed in contact with the upper part of the limb above the level of the water, and the other pole in the basin, the salt and water being thus converted into an electrode. As many elements as the patient can comfortably bear should be employed, and the current should be made and broken at frequent intervals, so as to get repeated moderate contraction of the limb. The patient should also move the digits."

Radiant heat is sometimes satisfactory in relieving the pain. In the severe form with necrosis, the pain must be relieved by local sedative applications; lead and opium lotions, fomentations, and morphia may be required.

Cushing advises a modification of Bier's treatment in order to re-establish the circulation. The limb is firmly bandaged for one or two minutes, until it is completely anæmic, the bandage is then relaxed, and a period of active hyperæmia succeeds the period of anæmia. The process is painful, but is of distinct benefit.

Local treatment of the gangrenous areas consists mainly in assisting the natural process of separation, as in the senile variety. The parts must be kept dry and aseptic as far as possible; heat, either dry or moist, is of service when the pain is severe. Radical treatment is rarely indicated.

Spreading Traumatic Gangrene belongs to an entirely different category. It is a form of gangrene following wounds contaminated with earth into which the bacillus of malignant œdema finds its way. This deadly disease should be suspected in cases of lacerated wounds and compound fractures when the limb becomes swollen and œdematous very shortly after the infliction of the injury, and when an emphysematous crackling can be felt on examining the tissues. Once established, the process spreads with fearful rapidity, and nothing short of immediate amputation can give the patient the barest chance. In cases where

this condition is suspected, cultures should be made from the wound, and the patient should be very closely watched; if the bacillus is found, or if the process spreads, the limb must be removed as near the trunk as possible. In spite of prompt treatment, death is the usual result.

W. H. Clayton-Greene.

GASTRALGIA.—For the type of gastralgia which is relieved by food or alcoholic stimulants and is made worse by tea or hot water, the most efficient treatment undoubtedly is morphine or heroin hydrochloride in small doses. Fifteen or twenty minims of the B.P. solution of morphine, or an equivalent solution of heroin hydrochloride diluted in water, and coloured or covered by the addition of a few drops of compound tincture of cardamoms, give immediate relief. Papaverine, one of the weaker alkaloids of opium, has lately come into favour for the treatment of this condition, on the hypothesis that it relaxes the spasm of the pylorus which is most probably the cause of the pain. Small doses of chloral hydrate and antipyrin have been recommended, and may be tried where the patient is intolerant of morphine or heroin hydrochloride.

In the type of gastralgia associated with anæmia, where the pain comes on immediately after food and is relieved by vomiting, the treatment should be rest in bed and the administration of iron. Food should be given at first in small quantities, such as 1 oz. of milk every hour, to coax the stomach by easy stages to bear ordinary diet, much as in the case of gastric ulcer. The aperient iron mixture given in cases of gastric ulcer should be supplemented by pil. ferri or Oppenheimer's biphosphates of ferrous carbonate, of which two should be given three times a day.

Robert Saundby.

GASTRIC CRISES.—Treatment consists in withholding all food and drink by the mouth, and the hypodermic injection of morphine or papaverine. If necessary, rectal feeding may be employed. (See also **TABES**.)

Robert Saundby.

GASTRIC ULCER (Medical Treatment) should always be treated in bed, and indeed it may be said that frequent vomiting is in itself a sufficient indication for sending the patient to bed. In nine cases out of ten the pain and vomiting stop after the patient is placed there, and the stomach tolerates diluted milk, e.g., 1 oz. of equal parts of milk and barley-water every hour.

Where there has been hæmatemesis within forty-eight hours, it is advisable to rest the stomach completely, and feed by the rectum. A nutrient enema is composed of one or two eggs beaten up with 4 or 5 oz. of milk* and a teaspoonful of dextrose, with a pinch of salt added; it should be injected slowly into the rectum. The bowel should always be cleared out every morning by a simple enema or an irrigation of normal saline solution. Such nutrient enemata should be repeated every four hours, and may be continued for three or four days. Many authorities recommend that the rectal feeding should be kept up longer, in order to permit the stomach ulcer to heal, but most admit that the time should not exceed ten days. As the main factor which prevents the healing of the ulcer is the depressed general health, and as the amount of nutriment absorbed from the rectum is small, continued rectal feeding does not seem likely to promote recovery, and more harm than good results from prolonging it beyond what is needed for safety. On the other hand, suitable stomach feeding never in my experience does harm, and if it should cause pain, the rectal feeding can always be resumed for another day or two.

During the first week the food must be liquid, and the quantity of milk and barley-water should not exceed 4 oz. each hour, a point to which it should be gradually raised from the initial 1 oz. Where it is thought desirable to increase the supply of nutriment, three or four eggs well beaten up may be added to the

* Native proteins are probably not absorbed from the large intestine.—AMERICAN EDITOR.

daily allowance of milk. In the second week, if there has been no return of symptoms, bread and milk, made with soft roll, may be added morning and evening, and custard pudding given in the middle of the day, the milk being continued. The patient should not be roused from sleep in order to take the milk at night during this course of treatment. In the third week he may have 4 oz. of chicken, minced, with a little mashed potato, and cocoa or milk tea (tea infused with milk) for breakfast, with soft roll and butter. In the fourth week he should be able to take ordinary food, so long as it is soft and well cooked; but if the teeth are defective, it must be minced or pounded.

The most useful medicinal treatment is iron combined with sulphate of magnesia, the latter being given in sufficient doses to keep the bowels open, constipation being generally present.

Bismuthi Carbonatis		Aquam Menthæ Piperitæ dest.	ad 3j
Magnesi Carbonatis	āā gr x		

Two tablespoonfuls three times a day or before each meal.

R Olei Olivæ	3j	Aquam	ad 3j
Pulv. Tragacanthæ	gr xx		

Two tablespoonfuls before food.

The administration of nitrate of silver in pills in the hope of stimulating the healing of the ulcer is futile, for the probability is that the pill does not dissolve in the stomach, and in any case the chances are greatly against the remedy coming in contact with the ulcer. Washing out the stomach with a solution of nitrate of silver, or the administration of teaspoonful doses of a $\frac{1}{2}$ per cent solution by the mouth, seems not warranted by our experience of the treatment of deep ulcers elsewhere. I have forborne to employ these remedies for a long time, and I have not found any sensible delay in the progress of my cases from their omission.

Recurrence of hæmorrhage indicates resumption of rectal feeding, stoppage of all medicine by the mouth, the application of an ice-bag to the epigastrium, and a hypodermic injection of morphia ($\frac{1}{8}$ gr.). The use of freshly-prepared sterile rabbit-serum by the mouth is worth trying: a teaspoonful three times a day for two or three days and then once daily for two or three weeks. (See ILEMATEMESIS.)

Frequently recurring hæmorrhage suggests the propriety of surgical interference, but this is rarely needed. When the stomach has been opened it has often been difficult to find the bleeding point, and few surgeons are anxious to interfere in these cases.

I have never known perforation to occur while the patient was under treatment in bed; but, whenever it does take place, it indicates surgical intervention without delay.

Perigastric adhesions, stenosis of the pylorus, and hourglass stomach can be remedied only by surgical means. Klemperer strongly advocates a trial of the hypodermic injection of thiosinamine (fibrolysin), which is said to soften and remove fibrous bands; it might be tried for a time in the absence of urgent symptoms. During the time the patient is kept in bed it is desirable to aid recovery by general massage.

The diet should be brought up to something like the normal standard before the patient is allowed to leave his bed, and after getting up, no variation should

be made for some weeks. If possible, a change to some bracing health resort should follow, and the aperient iron mixture should be continued until the anæmia has completely disappeared.

Robert Saundby.

Surgical Treatment.—Our conception of 'gastric ulcer' has entirely changed in recent years; formerly considered easy of diagnosis, it is now known to be difficult even in long-standing cases. For this reason the prognosis of cases not verified by operation is entirely a matter of conjecture.

Two distinct lesions are included under the term gastric ulcer: the acute ulcer, frequently multiple; and the indurated chronic ulcer, usually single. It is evident from the discrepancy between the sex-distribution in the medical and surgical statistics that there are two distinct conditions—one more common in women, in which acute ulceration followed by perforation may occur; the other more frequent in men, in which the immediate cause of death is not uncommonly hæmatemesis, and in which perforation is uncommon.

The cases formerly diagnosed gastric ulcer in young women are usually examples of extra-gastric disease, with, in many cases, acute gastritis or mucous ulcers due to septic infection. The relationship between the two groups is at present obscure, but it seems certain from the incidence of chronic lesions that, in the majority of cases, although symptoms recur, chronic gastric ulcer does not follow. Careful medical treatment of this group of cases, if the condition causing the gastric disturbance (septic teeth or chronic constipation) can be dealt with, is successful; but if disease of the gall-bladder or the appendix is responsible, treatment of these alone will cure.

In chronic gastric ulcer, in addition to the dangers from hæmorrhage, perforation, and malnutrition the result of stricture, there is the appreciable risk of the development of carcinoma.

Operative treatment should not be undertaken—except when perforation has taken place or in certain cases with hæmatemesis—until all septic foci in the mouth or elsewhere have been attended to, and the patient subjected to a thorough course of medical treatment. If this fails to relieve, or relapses occur, operation should be carried out. It offers the patient almost certain relief, with a more than 80 per cent prospect of cure, at a very slight risk. In no case should the surgeon set out to perform any stated operation; he must be prepared to change his plans, and to treat the disease causing the symptoms. It is never permissible, for example, to perform gastrojejunostomy in the absence of definite evidence of ulcer.

Before operation, the mouth should be carefully attended to and septic teeth treated. For the twenty-four hours preceding operation nothing but sterilized food is given, but the patient does not necessarily remain in bed. Gastric lavage is not carried out unless dilatation is present.

In opening the abdomen, an incision is made an inch to the right of the middle line; after dividing the anterior sheath of the rectus, the muscle is retracted outwards and its posterior sheath and the peritoneum incised in a line with the anterior. The whole stomach and duodenum are then examined from end to end. If an ulcer needing surgical treatment is present, it can always be seen or felt. Gastrojejunostomy should never be carried out unless the ulcer can be demonstrated. The condition of the gall-bladder, appendix, and lower ileum should always be investigated, and lesions treated.

Perforation.—Perforation, though usually acute, may be chronic, a subphrenic abscess forming. Immediate operation should be carried out. If, as is usual, the perforation is acute and on the anterior surface of the stomach, it may be excised, or buried with through and through stitches of chromic gut buried by a Lembert stitch of fine silk or thread. Other perforations should be looked for.

If there has been much peritoneal soiling, the extravasated fluid should be gently wiped away; irrigation should not be carried out. If drainage is necessary, this should be done by tubes inserted through a separate incision into the kidney pouch and pelvis as required, and the anterior wound closed.

When the ulcer that has perforated is a chronic one, it may be impossible to bury it. If the condition of the patient will admit, it should be excised; or, failing this, covered with an omental graft.

When the ulcer which has perforated is a chronic one, or when closure of the perforation produces deformity such as would interfere with the functions of the stomach, gastrojejunostomy should be carried out at the same time. It is unnecessary in acute ulcer. If the perforation is recent, search should be made for other abdominal disease.

Chronic Gastric Ulcer.—The ulcer should be infolded or excised, and gastrojejunostomy carried out. Simple chronic ulcers heal after gastrojejunostomy, no matter in what part of the stomach they are situated, provided that they are not adherent. In the common cases, in which a posterior ulcer has become adherent to the pancreas, perforation has usually taken place and the floor of the ulcer is formed by pancreas. These must be treated by excision, as should any ulcer in which there is any suspicion of malignancy. Gastrojejunostomy must be performed even if the ulcer is excised. Recurrence is frequent unless it is done. Posterior no-loop gastrojejunostomy is the operation of choice. If this is impossible, then the writer's anterior no-loop method should be carried out. The whole abdomen must be thoroughly investigated.

Hour-glass Stomach.—As a rule there is only one constriction present, that caused by the ulcer on the lesser curvature; occasionally pyloric stenosis is present in addition, as the result of a chronic duodenal ulcer. Gastrojejunostomy to the cardiac pouch should be carried out if no pyloric stenosis is present; where this complication exists, a gastrojejunostomy should be performed to each pouch. The result of surgical treatment is excellent.

Hæmatemesis.—Operative interference is *never* indicated in the hæmatemesis of young women. Bleeding is usually occurring from many foci, and continues unchecked in spite of gastrojejunostomy.

It is otherwise when the bleeding occurs from a chronic ulcer. The death-rate, apart from operation, is over 50 per cent. Operation should be carried out as soon as possible after the first hæmorrhage; this is usually within twenty-four hours. The bleeding point should be directly controlled by excising the ulcer or by ligaturing the vessel on either side of it, combined with inversion and gastrojejunostomy.

Post-operative Treatment of Gastric and Duodenal Ulcers.—As much water is given to drink as the patient wishes. Vomiting is unusual; if at all frequent or copious, the stomach should be gently washed out and kept empty. As soon as wished, Benger or Allenbury food is given, and food increased until at the end of the first week boiled chicken is being taken, but the wishes of the patient should be studied, and no effort made to hurry on to solid food. I allow the patient to get out of bed about the eighth day, and to leave hospital on the thirteenth or fourteenth day after operation.

For at least three months from the date of operation I enjoin them to be careful in their diet, to avoid roast beef, ham, and bacon, and to take a powder composed of equal parts of bismuth oxycarbonate, heavy magnesium carbonate, and sodium bicarbonate, one drachm three times a day between meals. The bowels should be kept regular, if necessary; when tolerated, liquid petrolatum acts excellently in these cases. In many patients, however, in whom constipation was a troublesome feature before operation, the action of the bowels becomes regular. Patients should be kept under observation for a considerable time

If complaint is made of gastric discomfort, a test meal should be given ; if the acidity is found to be above normal, a course of treatment should be adopted to diminish it.

Three complications may occur after gastrojejunostomy :—

1. *Vomiting*.—In patients in whom operation is difficult owing to their stoutness or to trouble with the anæsthetic, vomiting of large quantities of bile may occur in the first twenty-four to forty-eight hours. This I am accustomed to call paralytic regurgitant vomiting. It yields readily to lavage.

True regurgitant vomiting is the result of obstruction in the region of the anastomosis, and is extremely rare after modern operation. It is due to error in technique. Treatment consists in keeping the stomach empty by tube passed each night. As the quantity removed diminishes, the treatment is carried out on alternate nights, and then with gradually increasing intervals. If no diminution takes place, lateral anastomosis between the afferent and efferent limbs or, if this is impossible, duodenojejunostomy must be done.

A few patients complain of occasional morning vomiting of bile. As a rule no treatment is necessary. If it is really troublesome, a course of lavage will often relieve it.

2. *Diarrhœa*.—It has been stated that intractable diarrhœa may result. I have not yet come across this. In three cases after gastrojejunostomy for chronic gastric ulcer with a low acidity, diarrhœa developed ; in all it yielded at once to the administration of dilute hydrochloric acid.

3. *Jejunal ulceration*.—This is the complication most feared. It is at the present time met with in less than 2 per cent of the cases operated on for chronic duodenal ulcer. It will become still more uncommon if, at the first operation, the whole abdomen is investigated, other lesions treated, and care exercised in the supervision of patients after operation. The cause is probably that of the original ulcer. It is only met with after operation on patients in whom hyperacidity was present, and hence is more common after operation for duodenal ulcer.

Pain, one to three hours after food, often relieved by food, waking the patient about 2 a.m., and felt to the left of the umbilicus, is the common symptom of this complication. Perforation into the free peritoneal cavity is unknown after the posterior no-loop operation, but in a few cases a profuse hæmatemesis is the first symptom. Gastric acidity is always high.

Operation should not be delayed. In neglected cases perforation takes place into the colon, with the formation of a gastrojejunocolic fistula. No rules can be laid down. It is sometimes possible to excise the ulcer and to suture the opening in the jejunum, but more often the whole anastomosis has to be excised. In these cases both ends of the jejunum should be separately implanted into the stomach, so that the whole of the bile and pancreatic juice passes through it.

If thorough abdominal exploration was not carried out at the first operation, it should be done, and lesions in other organs dealt with.

James Sherren.

GASTRITIS, ACUTE AND CHRONIC.—The dietetic treatment should, as far as possible, involve rest to the stomach, and abstinence from all food which is irritating from its chemical composition or its mechanical state. A quite recent attack, of only a few hours' duration, may be successfully treated by drinking 20 or 30 oz. of warm water, so as to dilute the gastric contents, and if the pain does not subside, by emptying the stomach, either by tickling the pharynx, or giving a sulphate of zinc emetic (20 gr.) ; the food should be hot water, or milk diluted with two parts water, for the rest of the day, and on the following day only the blandest food should be taken.

The following articles of diet are forbidden to persons suffering from gastritis

in any form :—All fats, including butter, which should at most be taken very sparingly, pork, smoked and salted meats, ham, bacon, veal, salmon, mackerel, eels, lobsters, and crab ; all fried and greasy dishes ; porridge, brown bread, pastry, uncooked fruit ; all fruit containing seeds and skins, or until these have been removed ; nuts of all kinds ; raw vegetables, salads, radishes, cresses, mushrooms, carrots, turnips, parsnips ; pickles, sauces, pepper ; cheese, cream cheese ; malt liquors, spirits, port, madeira, sherry, Indian and Ceylon teas, iced water and iced creams.

During convalescence from an acute attack, and in chronic cases, the diet should be something like the following :—

Breakfast.—Toasted white bread ; white fish, boiled or broiled ; cocoa, coffee, or China tea infused with milk ; no butter.

Luncheon.—A slice of mutton, or a mutton chop without fat ; mashed potatoes ; milk pudding ; water or claret or still moselle and mineral water.

Tea.—China tea, infused with milk ; Madeira cake.

Dinner.—No soup ; white fish, boiled or broiled ; lean beef or mutton ; fowl or game lightly cooked ; mashed potatoes or any tender green vegetable ; baked custard or stewed fruit, without cream ; water or claret or still moselle and mineral water.

The following course of treatment will be found useful. Two 5-gr. blue pills should be ordered, of which the first should be taken at bed-time, and the second two nights later, the patient being told not to repeat these pills. Either the rhubarb and bismuth mixture, or the compound bismuth powder, should be given before each meal.

R Sodii Bicarbonatis		Mucilaginis Tragacanthæ	℥xv
Bismuthi Carbonatis	āā gr x	Aquam Ment hæ Piperitæ	ad ʒj
Pulveris Rhei	gr iiss		

Two tablespoonfuls to be taken before each meal.

R Sodii Bicarbonatis		Pulveris Rhei	gr iiss
Bismuthi Carbonatis	āā gr x	Pulveris Aromatici	gr v
M. Ft. pulv.	Mitte xii.	A powder to be taken in a little milk before each meal.	

Half a tumblerful of hot water should be sipped slowly the first thing in the morning, and to this may be added a teaspoonful or more of the effervescing sulphate of soda, if the bowels need assistance.

Chronic Catarrh of the Stomach.—In regulating the diet, those articles already enumerated which may cause irritation must be eliminated, and for a time a stricter regimen may be necessary. The two main lines of dietetic treatment are : (1) *Milk*, which should be diluted with barley-water or soda-water, and is preferably sterilized ; (2) *Minceed lean meat*, which should be prepared in the same way as the Scottish national dish called collops. This minced meat is eaten without condiments, bread, or vegetables, but hot water *ad libitum* may be allowed two hours after meals. Many cases which resist milk diet improve rapidly upon minceed meat, and it is, perhaps, most useful in cases where there is hypersecretion of gastric juice.

The most useful drugs are bicarbonate of soda, sulphate of soda, bismuth, magnesia, and mercury, the last in the form of calomel or blue pill. The treatment should commence by a course quite similar to that given in subacute gastritis ; but when the gastric irritability has been allayed, the following acid mixture may be usefully continued for some time :—

R Acidi Nitrohydrochlorici Diluti	℥x	Succi Taraxaci (B.P.)	ʒj
Tincturæ Nucis Vomiceæ	℥xxv	Aquam	ad ʒj

Two tablespoonfuls three times a day directly after meals.

This seems to be indicated where the urine deposits amorphous alkaline

phosphates; acidol tablets dissolved in half a tumblerful of *eau sucrée* fulfil the same object, and have the advantage that they can be carried in the pocket. If the patient is troubled by acid eructations, one of the following mixtures should be given:—

R Sodii Bicarbonatis		Mucilaginis Tragacanthæ	℥xv
Bismuthi Carbonatis		Aquam Menthæ Piperitæ dest.	ad 3j
Magnesiæ Carbonatis	āā gr x		
Two tablespoonfuls three times a day or before each meal.			
R Olei Olivæ	3j	Aquam	ad 3j
Pulveris Tragacanthæ	gr xx		
Two tablespoonfuls before each meal.			

If the appetite is bad, give the following:—

R Sodii Bicarbonatis	gr x	Tincturæ Zingiberis fort. (50%)	℥v
Tincturæ Rhei	℥xxx	Infusum Gentianæ Co. (N.F.)	ad 3j
Two tablespoonfuls before each meal.			

The bowels must be kept freely open, if necessary by the use of aperients, such as effervescing sulphate of soda or Rubinat water; or in patients of spare and nervous habit, a pill of aloes or cascara.

Such cases are treated successfully at many mineral-water-cure places, notably at Carlsbad, Homburg, Kissingen, Neuenahr, Vichy, and Châtel-Guyon.

Robert Saundby.

GASTROPTOSIS.—In the treatment of gastroptosis there are three objects to be aimed at: (1) The cure of the underlying neurasthenia; (2) The removal of any functional disorder of the stomach which co-exists; (3) The correction, if possible, of the malposition of the organ.

1. The great majority of patients who exhibit gastroptosis are the subjects of neurasthenia, to which, and not to the displacement of the stomach, many of their troubles are due. When the neurasthenic symptoms are at all pronounced, it is advisable to begin treatment by a rest-cure (see NEURASTHENIA). This will comprise rest in bed for at least four weeks, with abundant feeding, massage, the use of enemata to correct constipation, and, for the first week at least, the application of hot fomentations to the abdomen. The help of a good nurse who understands massage is essential, but it is not imperative that the treatment should be carried out away from home, although the visits of relatives and friends must be rigidly restricted.

The diet must be abundant, six small meals of easily digested food being given in the day, and bulky, innutritious articles (e.g., fruits and green vegetables) avoided. Fluids and solids should, as far as possible, be given separately. Cream and other forms of fat should be taken freely.

Bromides are usually required during the first week or two of the rest-cure. Massage is performed twice daily in the usual way, but the use of electricity may be dispensed with.

2. The usual co-existing functional disorders of the stomach are defective motility (atony) and hypersecretion. Some degree of gastritis, however, as manifested by a furred tongue, loss of appetite, and nausea, is often present when the patient first comes under treatment. This should be remedied by the administration of a rhubarb and soda mixture with the addition of a grain of blue pill and three grains of compound rhubarb pill every night. When the tongue has become clean, one can proceed to deal with the atony and any disorder of secretion which may be present. As regards the former, abdominal massage is of great help, and with it may be combined the use of the sinusoidal electric current. The medicinal treatment should consist in the administration of an alkaline bitter mixture with a little nux vomica before meals, or an acid and nux vomica mixture after food (see DYSPEPSIA, ATONIC). Some writers

recommend also the use of tincture of physostigmine (B.P.) in 10 to 15 min. doses twice or thrice a day as a muscle tonic. Carminatives may also be required from time to time for the relief of flatulence (see FLATULENCE). Lavage of the stomach should be avoided. If hyperacidity be present, 15 gr. of carbonate of bismuth or carbonate of magnesia should be added to each dose of the alkaline bitter mixture.

3. The replacement of the stomach can only be partially effected in most cases, but the deposition of intraperitoneal fat and the restitution of the abdominal wall which the over-feeding and massage bring about, help to lift it up to some extent. Gastropexy, though sometimes recommended, is rarely if ever necessary; gastro-enterostomy should never be performed.

As the result of the four weeks' rest-cure, combined with as much of the above special treatment as the complications present indicate, the patient should gain about 12 lb. in weight. She should then be fitted with a well-made abdominal belt, belt-corset, or other form of support, and may go away for a change of air. During convalescence and for many months after returning to ordinary life, however, one must insist upon abundance of rest, and especially upon lying down for half-an-hour after meals. The diet should continue to be abundant, and food should be taken between meals, but the amount of fluid taken at meals must be restricted. The practice of abdominal exercises may be continued with advantage, and the belt or surgical corset must be worn constantly. A further gain in weight of 10 lb. or more should be looked for in the first year after the rest-cure. In those cases in which the symptoms are not sufficiently severe to necessitate a rest-cure, or where the latter is impracticable, the treatment should consist in (1) An abundant but dry diet; (2) Lying down after meals; (3) Abdominal massage and exercises; (4) The use of an abdominal belt or surgical corset; (5) The administration of such drugs as are of use in atonic dyspepsia and in flatulence. (See also KIDNEY, MOVABLE.)

Robert Hutchison.

GASTROSTAXIS.—The immediate treatment of this condition is that of hæmatemesis (q.v.). Three days after the cessation of the bleeding, feeding by the mouth may be begun, and for the first week should be the same as in a case of gastric ulcer (q.v.). After this, if all is going well, the diet may be pushed on rapidly, and in most cases pounded meat and fish may be begun by the end of the second week.

Bismuth in full doses should be given at first, but after a week it should be combined with iron, e.g.:—

R Bismuthi Carbonatis | Ferri Carbonatis Saccharati āā gr xv
Thrice daily.

Or an aperient iron mixture may be given:—

R Ferri Sulphatis	gr. iij	Syrupi Limonis	ad ʒj	
Acidi Sulphurici Diluti	℥ xiij			Aquam Ment hæ Piperitæ
Magnesii Sulphatis	gr. xxx-ʒj			

Thrice daily after food.

The after-treatment is the same as that of gastric ulcer. *Robert Hutchison.*

GENU VALGUM.—(See KNOCK-KNEE.)

GIDDINESS.—(See VERTIGO.)

GLANDERS.—In the *acute* form of the disease, all that can be done is to deal with symptoms as they arise. Abscesses must be opened and drained, and treated antiseptically. The patient should be isolated, and those in

attendance upon him should be very careful not to inoculate themselves with the disease.

In the *chronic* form, every effort should be made to get rid of the local lesions by excision and antiseptic applications. The nasal passages, if affected, should be washed out freely and frequently with antiseptic solution. Bendall recommends the internal administration of benzoate of soda at frequent intervals. Babes and Bonome advise the subcutaneous injection of $\frac{1}{20}$ to $\frac{1}{15}$ c.c. of mallein, at intervals of two or three days, for two months or so. After the early injections a reaction, local and general, follows; but after a time this does not occur. Such treatment is a form of vaccination. Lastly, a vaccine of dead *Bacillus mallei* has been tried in a few cases with some measure of success. It is very important to place the patient under the most favourable conditions as regards food, fresh air, etc. (See also SPECIFIC THERAPY.)

E. W. Goodall.

GLAUCOMA.—This is a condition of increased intra-ocular tension which is due to the eye containing too much fluid. It contains too much, because the fluid cannot get out of the eye. The fluid is secreted by the ciliary body, and normally should pass forwards through the pupil into the anterior chamber, through the angle of which it should get out of the eye by means of the canal of Schlemm. In every case of glaucoma there is some block in the circulation of this fluid. Thus, in primary glaucoma the block is due to apposition of the iris to the back of the cornea at the angle of the anterior chamber, so preventing the fluid passing into the canal of Schlemm; again, in iritis the pupil may become completely bound down to the lens, so that the fluid cannot pass from the posterior to the anterior chamber.

Before we can treat a case of glaucoma we must ascertain the exact cause of the increased tension, for in different cases the treatment may vary diametrically. Taking the above examples: in primary glaucoma, atropine, by dilating the pupil, will still further block the angle and may blind the eye, while eserine, by contracting the pupil, will tend to draw the iris away from the back of the cornea and relieve the tension; on the other hand, in iritis, with the pupil bound down to the lens, atropine, by breaking down the adhesions, may restore the circulation again and cure, while eserine, by contracting the pupil and increasing the congestion, will only make matters worse.

Primary Glaucoma (i.e., where there is no evidence of previous disease to account for the glaucoma).

DIAGNOSIS.—The chief difficulty in diagnosis occurs in distinguishing acute or sub-acute glaucoma from iritis.

In *glaucoma* there is increased tension. In *iritis* the tension is usually normal; but for those who cannot rely on their estimation of tension, there are other valuable points on which to base the diagnosis. In both these conditions there may be severe pain, coming on more or less suddenly, both in the eye and radiating over the brow, some failure of sight, circumcorneal injection, and dislocation of the iris. But apart from the tension, it is the *pupil* which will in most cases give us the necessary clue.

In glaucoma the pupil is dilated—often pear-shaped. In iritis the pupil is contracted.

Other distinguishing points are the following:—

In *glaucoma* the circumcorneal congestion is a dusky purple, the anterior chamber is as a rule shallow, there are no spots of exudation on the back of the cornea, the iris is not bound down to the lens, there is generally a history of previous attacks of misty vision, with the appearance of coloured rings or halos round lights, possibly with some pain, which lasted a few hours and then passed off. In *iritis* the congestion is bright red, the anterior chamber is normal or deep, there are often spots of exudation to be made out (with a bright light and a magnifying glass) on the back of the cornea, or the pupil is in places bound down to the lens. If there have been any previous attacks of iritis, the failure in sight due to vitreous opacities, etc., will have lasted for weeks, not hours, and there will not have been halos. Halos are rarely seen except in glaucoma and in conjunctivitis; in this latter condition they are due to a film of mucus over the cornea. Examination of the other eye may reveal some signs either of glaucoma or previous iritis.

TREATMENT differs only in degree, according to whether the disease is acute, subacute, or chronic. In each, the cause of the increased tension is the blocking of the exit of the fluid of the eye at the angle of the anterior chamber by the apposition of the iris to the back of the cornea; our aim must therefore be to restore the circulation of the fluid in the eye, and so reduce the tension, either (1) By opening up the angle of the anterior chamber and so allowing the fluid to escape from the eye by the normal channels, by means of myotics or the performance of an iridectomy; or (2) By making some vicarious exit for the fluid by means of some form of filtering scar, such as trephining, sclerotomy, or Herbert's or La Grange's operation.

Myotics are very useful to reduce the tension in the acuter cases, and to tide them over till an operation can be performed, but as a rule they are to be looked upon as only temporary measures, and some operative treatment must be resorted to in order to bring about a permanent cure. The only exception to this is in elderly people with very chronic glaucoma: myotics may hold the glaucoma in check for years; but even here, if the field contracts, an operation should be done.

In addition to local treatment, it is very important to attend to the general health of the patient, especially with regard to lowering any increased blood-pressure, which should be measured in all cases. Diet should be restricted, especially in regard to meat and stimulants, the latter being avoided altogether when practicable. All kinds of mental anxiety should, whenever possible, be relieved, constipation avoided, only moderate use of the eyes allowed, and this with properly correcting glasses.

1. *Threatened Glaucoma.*—In the early stages of glaucoma—when only attacks of misty vision and halos have occurred—even though the vision is $\frac{6}{6}$, and there is no contraction of the field, as soon as the diagnosis is certain, a trephine or an iridectomy should be done at once. One never knows how severe the attack may be when it occurs, and how much it may impair the sight. Cases operated on early do exceedingly well. It is a great mistake to postpone operation till the vision has definitely begun to deteriorate. This is especially true where one eye has had an acute attack, or is blind from glaucoma, and the good eye has begun to show symptoms. The good eye should be operated on without delay. Some surgeons regularly advise operation in both eyes, even though the symptoms have occurred only in one.

Until the operation takes place, the pupil must be kept contracted with eserine, 1 or 2 gr. to the ounce, instilled three times a day. The weakest eserine that will keep the pupil contracted should be used, and it may be combined with cocaine, in the proportion of 1 of eserine to 3 of cocaine.

2. *In an Acute or Subacute Attack,* treatment must be prompt and energetic; every hour of increased tension may cause irreparable damage to the retina and optic nerve. On the other hand, the reduction of tension must not be too sudden. It is much better to reduce the tension by eserine and leeching before operating, so that the fall of tension at the time of operation may be as little as possible, otherwise some retinal or choroidal vessel may give way, and an intra-ocular hæmorrhage occur, which will cause complete loss of the eye.

The patient should be in bed, two leeches applied to the temple, and eserine drops (3 or 4 gr. to the ounce *) instilled every quarter of an hour for the first hour, and later every hour, until the tension falls.

A purgative should be administered, and, if necessary and not otherwise contra-indicated, an injection of morphia—to give the patient some much-needed

* Sometimes eserine drops, 4 gr. to the ounce, cause very severe pain; if this persists, weaker drops gr. 2) must be substituted.

sleep. Stimulants should be avoided as far as possible, unless there is much collapse, when they must be given. If the tension comes down, it is better to postpone operating for at least twenty-four hours, to allow the patient and the eye to recover from the shock of the acute attack, the eye meanwhile being kept under the influence of eserine. The operation is then performed under the most favourable conditions. If, however, in spite of the above treatment, the tension has not come down after about six hours, an operation must be performed forthwith.†

Iridectomy is still the operation usually preferred in acute glaucoma, and gives excellent results, though some surgeons prefer trephining even for these cases.

Patients who have had one acute attack and have got over it, should have an operation performed without delay; since, if this is not done, a return of the tension is bound to occur, and may possibly happen at a time when the patient has no eserine to use, and is away from skilled aid, with the result that the vision may be seriously impaired, or even lost. The risk of the operation in skilled hands is less than that of leaving the eye alone. (*Vide infra*.)

3. *Chronic Glaucoma*.—It is in this group of cases that most surgeons, at the present time, prefer trephining to iridectomy, and especially in the most chronic cases (glaucoma simplex), in which the tension may never be found to be definitely raised, and no attacks of mists or halos are complained of; iridectomy, though it sometimes succeeds, does not hold out the same satisfactory chances of success as it does in the more acute forms, while trephining is often successful. As mentioned above, there are certainly cases where myotics alone (eserine or pilocarpine) have kept the field and acuity of vision practically unimpaired for years; but on the other hand, many treated in this way are seen in which either the drops are not used regularly, or a very troublesome eserine irritation is set up, or again, the myotic does not keep the disease in check, and the sight goes from bad to worse: so that in most cases it is safer to perform an operation as soon as possible.

Warning.—Before an operation is performed, it should be explained to the patient in most cases: (a) That there is a certain amount of risk in the operation. (Eyes have been lost from an intra-ocular hæmorrhage—to mention only one unavoidable accident); (b) Glasses will have to be worn after operation, to correct the astigmatism (though this is slight in the case of trephining); (c) Vision, except in the acute cases, will probably not be improved—it may be slightly worse, owing to the astigmatism, and the dazzling due to the irregular pupil. But these considerations are quite overbalanced by the fact that, if left alone, the eye will go blind; whereas the operation will probably save the sight for the rest of the patient's life.

Trephining is not so simple an operation as it is sometimes described, and should not be undertaken lightly. There are many complications which may arise during the operation itself; and even if to all appearances perfectly done, the tension sometimes returns, or a troublesome iritis is set up which may materially impair the sight, to mention only two of the commoner troubles. For details of the operation, see ophthalmic text-books.

The care of a case which has been trephined is much the same as after iridectomy (*vide infra*). The only difference is that it is well to keep the pupil of the operated eye well dilated with atropine till all signs of redness have disappeared, in order to prevent iritis.

Trephining is, as a rule, a very successful operation; it leaves little or no astigmatism, the small button-hole iridectomy causes no dazzling, and if the tension is not relieved the operation can easily be repeated.

† Before doing the iridectomy in these cases, the tension should be first lowered by a posterior sclerotomy.

Iridectomy for glaucoma is a highly specialized operation. When the anterior chamber is very shallow, the incision becomes one of the most difficult procedures in ophthalmic surgery. If the knife goes too deep, it may easily pass through the iris and prick the lens, causing traumatic cataract, and generally loss of the eye; if it does not go deep enough, the cornea is tunnelled, and the anterior chamber is not reached. Again, the cutting of the iris does not consist in simply cutting off any portion of iris that may be grasped in the forceps; unless the iris is properly and freely torn away from its root, and the angles carefully replaced, the probability is that the operation will fail. Hence the importance of the operation being undertaken only by a surgeon skilled in ophthalmic practice. For details of the operation, see ophthalmic text-books.

Management of a case of Iridectomy.—There must be complete rest in bed for from five to six days, with strict nursing, the patient not being allowed to sit up till after the fourth day. Both eyes are bandaged for three days; after this the unoperated eye may be freed. A drop of eserine solution (2 gr. to the ounce) is instilled into the unoperated eye both at the time of the operation and daily for at least a week afterwards, to prevent an attack of glaucoma being induced in this eye.

The operated eye is dressed every day; warm boracic lotion is used to wash away any discharge from the lashes and lids, and a little allowed to pass into the conjunctival sac; great gentleness and strict antiseptic precautions must be exercised.

If no pain is complained of, no extensive examination of the wound is made until the fourth day. If the wound is flat, and the anterior chamber has re-formed, the bandage may be dispensed with during the day at the end of the week, dark glasses being worn; but a pad and bandage must be used at night for at least another week.

Complications.—If the anterior chamber does not re-form, the patient must be kept longer in bed. If the wound tends to gape, the bandage must be worn for longer than a week. If iritis or cyclitis supervenes, leeching to the temple and hot bathing should be used. If the wound bulges, and the lens presents, the lens must be removed.

When iridectomy fails to relieve the tension, eserine drops (2 gr. to the ounce) are given. If the tension still remains too high, trephining or one of the other forms of sclerotomy should be performed, and this can be repeated if unsuccessful at the first attempt. Very gentle massage of the eye by the patient himself, for three or four minutes twice a day, is effective in some cases.

If eserine causes irritation (conjunctivitis and eczema of the lids), nitrate of pilocarpine (2 to 4 gr. to the ounce) should be substituted: pilocarpine is less powerful but not so irritating as eserine. The skin of the lids should be treated with zinc oxide or calamine ointment, and the conjunctiva with a lotion of boracic acid (10 gr.) and zinc sulphate ($\frac{1}{2}$ or 1 gr. to the ounce).

Blind and painful glaucomatous eyes should be excised.

Secondary Glaucoma (i.e., where the glaucoma is secondary to some other disease).

1. *Iritis* is occasionally complicated with glaucoma (see IRITIS):—

a. When the margin of the pupil is completely bound down to the lens (complete annular synechia), the fluid secreted by the ciliary body, being unable to pass through the pupil, collects behind the iris and balloons this forwards (Bombé iris). Our object in treatment must be to restore the circulation of fluid, either by breaking down the adhesions with atropine, or, failing this, by making some opening in the iris by iridectomy or quadruple puncture.

Atropine ointment (4 gr., or, if not strong enough, 8 gr. to the ounce) combined with cocaine (10 gr. to the ounce) is used every half hour for the

first three hours, and later, four to six times a day, combined with leeching to the temple, hot applications to the eye, and a brisk purge. If atropine fails to break down the adhesions and thus reduce the tension, some operation must be performed. When there is severe iritis a quadruple puncture is indicated,* to be followed later, when the eye is quiet, by an iridectomy. In the more chronic cases, iridectomy may be performed with a good chance of success.

b. When the pupil is not bound down to the lens, and the anterior chamber is deep, the increased tension being due to the blocking of the filtration area by inflammatory exudates, the tension must be met with leeching, purging, and atropine (but atropine in these cases must be used sparingly, just sufficient to keep the pupil moderately dilated). If this fails, paracentesis of the cornea must be performed, and this can be repeated several times, if necessary.

2. *Glaucoma frequently follows Wounds of the Cornea, or Perforation of a Corneal Ulcer, when the pupillary margin of the iris becomes included in the corneal opening.* An iridectomy must be performed as soon as the conjunctival sac is clean.

3. *Wounds of, or Operations on, the Lens* may cause glaucoma, quite apart from any iritis which the trauma may have produced. After needling the lens, or after accidental wounds, the soft lens matter may either block the pupil or collect in the anterior chamber, and thus give rise to increased tension. The treatment consists in keeping the pupil dilated with atropine, and letting out the soft lens matter by a curette evacuation. Sometimes a tag of lens capsule becomes adherent to the corneal wound after needling, or after extraction of cataract, which by dragging on the iris causes glaucoma. Eserine should be tried first; but if this fails, the capsule should be divided with a cutting needle.

4. *Dislocation of the Lens* may cause glaucoma. (a) Dislocation into the anterior chamber. Eserine must not be given, but the lens should be extracted. (b) Lateral dislocation. Eserine should be tried, and if it fails, trephining or iridectomy and removal of the lens with the scoop should be carried out. (c) Dislocation into the vitreous. In this case the lens cannot be removed. If eserine fails, trephining affords the best chance of saving the eye in this very hopeless condition.

5. *Glaucoma associated with Detachment of the Retina.*—Whenever this occurs, we must examine carefully for evidence of *intra-ocular new growth*. Even in doubtful cases the eye should be excised without delay.

6. *Glaucomatous Eyes associated with Cataract, and no Perception of Light,* should be suspected of new growth, and excised.

Buphthalmos (Glaucoma occurring in childhood, causing enlargement of the whole globe). The glaucoma may be primary or secondary. Where primary, trephining, Herbert's or La Grange's operation with or without iridectomy, or a sclerotomy, holds out the best chance of retaining vision, and should be done as early as possible. Where secondary, cases should be treated on the lines mentioned above.

W. Tindall Lister.

GLÉNARD'S DISEASE.—(See GASTROPTOSIS.)

GLYCOSURIA.—(See also DIABETES MELLITUS.) Transient glycosuria requires no treatment other than that which is indicated for the disease with which it is associated. Permanent glycosuria such as is met with in elderly, gouty, obese, or alcoholic subjects cannot be clearly distinguished from true

* If iridectomy is performed in the presence of acute iritis, the coloboma will probably be filled up with lymph, and a more severe, possibly a disastrous, iridocyclitis is liable to be set up.

diabetes, and must be treated on the same lines as the latter (q.v.). In the majority of instances it will be found that such cases belong to the alimentary type, and have some tolerance for carbohydrates; they should, therefore, be dieted in the same way as mild cases of true diabetes. Seeing, however, that alcohol undoubtedly plays a part in the production of some cases of glycosuria, it should always be banished from the diet. Spa treatment agrees well with such patients: Carlsbad, Vichy, and Neuenahr being the most suitable places. The same drugs may be tried as in true diabetes.

For the treatment of the most common complications (ECZEMA, CARBUNCLE, GANGRENE, CATARACT, etc.), see special articles. *Robert Hutchison.*

GOITRE, EXOPHTHALMIC.—In exophthalmic goitre the best results are to be obtained by a judicious combination of hygienic measures with *x*-ray, electrical, and medicinal treatment.

The hygienic treatment consists mainly in regulating the amount of rest, exercise, feeding, and fresh air suitable for each case. In very severe cases, at the commencement of the treatment of cases of moderate severity, and during the acute exacerbations which may occur in any case, complete rest in bed is essential, and may be continued for from two to six weeks or longer, according to the severity of the symptoms and the progress made. The rest should be combined with feeding on a generous diet, consisting chiefly of milk, carbohydrates, and fats, regulated in amount by the degree of emaciation which has taken place. The quantity of milk to be taken in different cases may thus vary from 2 to 6 pints in the twenty-four hours. Fish and meat should be allowed only in small amounts. In carrying out this modified "rest-cure," it is not generally advisable to isolate the patient.

With patients who are able to go about, and who have already been treated by complete rest, it is most important to regulate the mode of life. Twelve hours' rest in bed at night is required, from ten to ten being a convenient time. In some cases, an additional rest for half an hour to an hour after lunch, and before dinner in the evening, is advisable. A quiet life in the country is most suitable, and should be recommended when possible. It is a great advantage if the larger part of the day can be spent out of doors or in an open-air shelter. In fact, the open-air life such as is practised in the treatment of pulmonary tuberculosis at a sanatorium is extremely beneficial in many cases. A dry, bracing, inland climate is the most suitable. Marine climates should not be recommended, as in many cases the symptoms are aggravated by a visit to the seaside or by a sea-voyage. All undue excitement, and over-exertion, must be sedulously avoided. As exophthalmic goitre not infrequently occurs in young women of much natural ability, who are leading an active and useful life, it is necessary in each case to give exact directions as to what may or may not be undertaken. Walking is the most suitable form of exercise, but the pace should be limited to two miles an hour, and the distance regulated according to the effect which the exercise produces upon the pulse-rate. The more active movements entailed by cycling, riding, or playing tennis, are unsuitable, and quicken the pulse far too much. Uncongenial social duties, concerts, theatres, and large gatherings of people, are all unsuitable for these cases.

X-ray Treatment.—The systematic application of *x*-rays to the thyroid gland is of great value in the treatment of Graves's disease. The rays must be passed through a suitable filter of aluminium or boiler-felt, so that only the β and γ rays pass through to the gland. As a rule one Sabouraud unit should be given at each sitting. This dose may be given twice a week at first and once a week later on. In some cases a course of three or four months will suffice, in others the treatment may have to be continued for a year. In the majority

of cases gradual, and in some, rapid, improvement takes place. The x rays probably induce atrophy of the abnormal secreting cells, and stimulate the development of an interalveolar fibrosis.

Electrical Treatment.—A very useful method of treatment, especially when x rays are not available, is by the prolonged daily application of a moderate faradic current to the neck. Two flexible electrodes, some four inches long and two wide, are applied, the one over the goitre in front and the other at the back of the neck, and fixed in position by means of straps and buckles at the sides. These are connected with the secondary circuit of a dry-cell faradic battery, a water rheostat being included in the circuit, so that the strength of the current can be modified as desired. The current, which should be just strong enough to produce a prickling sensation in the skin, may be applied from one to two hours morning and evening. This treatment should be continued steadily for three or four months at a stretch. The patient readily learns how to use the battery, and is then able to carry out the treatment without difficulty in her own home. (See also ELECTROTHERAPEUTICS.)

Medicinal Treatment.—A large number of drugs have been employed in the treatment of exophthalmic goitre; only a certain number of these have been of any real service, some in the routine treatment of the malady, others in the alleviation of the special symptoms.

One of the most useful drugs is arsenic, which may be given in nearly all cases with advantage. The best results are obtained by small doses continued over a long period with regular intermissions. As a rule 3 to 5 min. of liquor potassii arsenitis given thrice daily after food will suffice. It is a good plan to omit the arsenic for one week in each month, but to continue the treatment in this manner for from six to twelve months. Belladonna has been found to do good by many, but I find that patients often object to taking it continuously in sufficiently large doses, owing to the discomfort produced when its physiological effects are felt. It seems probable, though actual proof is lacking, that its beneficial effect is due to a diminution in the hypersecretion of the thyroid gland, so that it should be given in increasing doses until well-marked dryness of the mouth is produced. Sodium phosphate has been strongly recommended by some observers, in doses of from 15 to 60 gr. three times a day. I have not myself noticed any marked benefit produced by its use. In cases in which the pulse-rate is high, tincture of convallaria may be given in combination with one or other of the above drugs, in 10 to 15-min. doses, as it appears to have a better effect in reducing the frequency of the pulse than the other cardiac tonics. Where there is marked dilatation of the left ventricle with relative mitral incompetence, digitalis or strophanthus may be used with, or instead of, the convallaria. When nervousness is a specially marked feature, potassium bromide may be given in 10 to 15-gr. doses for a time. Suprarenal and thymus tablets (5-gr.) have appeared to do good in some cases, and in one of my cases all the symptoms of the disease, with the exception of the exophthalmos, disappeared while the patient was taking thymus tablets over a period of many months. Iodine should not be given internally in any form, as it is apt to increase the secretory activity of the thyroid gland. Thyroid extract should of course never be employed, as it only adds fuel to the fire and aggravates the symptoms.

Urgent special symptoms at times require treatment. Sudden attacks of diarrhoea should be treated by rest in bed, a milk diet, and the administration of laudanum (3 min.) with dilute sulphuric acid (20 min.) in a mixture three or four times a day. Vomiting is a serious symptom, and sometimes persists, in spite of all treatment, until the patient dies from exhaustion. Morphine, given either hypodermically or in a suppository, is the most efficient drug in the treatment of this kind of vomiting. In some cases, hypodermic injections of pituitary

extract have checked the vomiting. In severe cases, saline infusions might be of service, as the vomiting is probably due to a toxæmia. Very severe attacks of palpitation are most promptly relieved by the application of cold, in the form of an ice-bag to the præcordium.

Serum Treatment.—Various endeavours have been made to prepare an anti-toxic serum which would neutralize the toxæmic condition due to the excessive thyroidal secretion. In one direction it was assumed that, after removal of the thyroid gland, certain substances, which would normally have been destroyed by the thyroid secretion, accumulated in the blood, and that this blood, or a serum prepared from it, might be used conversely, as an antidote to the excess of secretion present in exophthalmic goitre. Ballet and Enriquez employed the serum of dogs from which the thyroid gland had previously been removed. Moebius, working on the same lines, made use of a serum obtained from the sheep several weeks after thyroidectomy, and reported favourably upon the results obtained by giving it in 5-min. doses three times a day. This serum, as prepared by Merck, can now be obtained under the name of "antithyroidine." Some observers have reported favourable results from its use. I have not been able to trace any special effect in the cases in which I have employed it, and Dr. Hector Mackenzie, after a most extended trial, came to a similar conclusion. Lanz, following up the same idea, has advocated the use of the fresh milk of a goat from which the thyroid gland had previously been removed. He obtained good results in six cases. The whole of the milk of one goat should be consumed by the patient in the twenty-four hours. This treatment is somewhat difficult to carry out, and some patients take a dislike to the goat's milk. When it cannot be obtained fresh, the dried milk, which is sold under the name of "rodagen," may be used instead, and very good results have been reported after taking it in $\frac{1}{2}$ -dr. doses three times a day, and I have seen marked improvement take place. In one case, however, the patient developed heart-block, while taking 1 dr. three times a day. The dried blood of an animal from which the thyroid gland has been removed, which is sold under the name of "thyroidectin," may be given in 5-gr. doses in a capsule three times a day. Good results have been obtained in some cases. Attempts have also been made to produce a serum which is thyrotoxic; that is to say, capable of bringing about destructive changes in the hypertrophied thyroid gland by a process of cytotoxicity. To this end, preparations of the thyroid gland of one animal have been injected into another animal, in the hope that in this way specific cytotoxicins might be produced in the serum of the second animal. Serum prepared in this way has not proved to be of any special service.

In conclusion, it may be stated that at the present time the best results are obtained by a combination of general hygienic treatment with the use of x-rays, electricity, and certain drugs as described above, and that as yet no serum or other animal product has been found to give uniformly better results than these.

Surgical Treatment.—(See also separate article.) Cases of exophthalmic goitre bear all operations badly, and the mortality after operations upon the thyroid gland in this disease has been high in this country. Recent improvements in the method of inducing anæsthesia, and the adoption of the principles of anoci-association, as recommended by Crile, have diminished the risk of operation in these cases in which nervousness is such a prominent symptom. Thus, Prof. Kocher has operated on 469 cases of Graves's disease, with a total mortality of 3·4 per cent. In mild cases no operation is required, as the prospects of recovery under medical treatment are good. In severe cases no operation is advisable unless medical treatment fails after a fair trial. It is in selected cases of moderate severity, with no serious cardiac disease, and in the wage-earning classes especially, that operative treatment may be recommended.

The most simple procedure appears to be to ligature the blood-vessels and the nerves of the superior pedicle, first on one side, and then, after an interval, on the other, so as to exclude nerve influence and diminish the blood-supply to the goitre. In some cases marked improvement follows. On the whole, the removal of one lobe of the enlarged gland has yielded the best results. In some cases complete recovery has resulted, and in others marked improvement.

George R. Murray.

GOITRE, SIMPLE PARENCHYMATOUS.—In certain cases of simple parenchymatous goitre occurring in young adults, much may be done by medical treatment in the early stages. In cases of long standing, and in those in which much fibrous tissue has developed, medical treatment has little if any effect, and if the goitre is large or causes inconvenience by pressure, a portion of it should be removed by operation. The favourable cases for medical treatment are those of simple parenchymatous goitre, which not infrequently occurs in adolescents and young adults. There is a uniform general enlargement of the gland, which develops gradually and painlessly; at first there is merely a slight fullness of the front of the neck, which may cause no inconvenience. As the goitre increases, it attracts attention by its size and the increasing tightness of the collar. If it grows still further, it may cause dyspnoea by compressing the trachea. It is probable that this growth of the gland is a true hypertrophy which occurs in response to some demand for an increased supply of its secretion. In some cases, however, it appears as if the hypertrophy, once started, goes on increasing until it surpasses physiological limits, becomes pathological, and does not subside without special treatment. If, in these cases, we give thyroid extract, we satisfy the demand for an increased supply of thyroïdal secretion from an external source, so that the gland is able to rest and undergo a partial atrophy, with a corresponding diminution in size. This course of events is analogous to that which takes place in the hypertrophied mammary gland during lactation, where, as soon as the demand for its secretion ceases, when the child is weaned, the gland returns to a resting condition and decreases in size.

In selecting cases for this treatment, it is important to make sure that no symptoms of exophthalmic goitre are present, such as frequent pulse, tremor, or nervousness, which would only be aggravated by thyroid treatment. In carrying out the treatment, it is advisable to begin with small doses. From two to five grains of dry thyroid (*glandulæ thyroideæ siccæ*) may be given each night at bed-time, either as a powder or tablet. In many cases this daily dose has proved quite sufficient, in others it is necessary to increase it to twice, or even thrice a day. As long as the pulse is not accelerated more than fifteen or twenty beats a minute, this dose may be continued. In a favourable case, the diminution in the goitre takes place rapidly; thus, in one of my cases the circumference of the neck at the commencement of the treatment on March 21st was $16\frac{1}{2}$ inches, on April 4th it was 14 inches, and on June 9th, 13 inches, a diminution of $3\frac{1}{2}$ inches in less than three months. By this treatment the goitre may be reduced to two-thirds, one-half, or one-third of its former size, or it may entirely disappear, and the symptoms caused by its presence are relieved, or removed altogether. In some cases the goitre may develop again when the treatment has been discontinued for a few weeks or months. When this occurs the size can be readily reduced again by a second course of treatment.

If the patient is living in a goitrous district, he should leave it, if possible, for a time. If this is not possible, careful attention must be paid to the character of the drinking water. Endemic goitre, as is well known, is due to some impurity

in the water. The nature of the active agent in the production of goitre is still unknown. It is, however, either destroyed, or at any rate rendered harmless, by boiling or distilling the water. It is therefore most important in all cases which arise in a district in which the disease is endemic, that the patient should drink only water which has been either boiled or distilled.

Iodine, in one form or another, has long been used with success in the treatment of simple goitre. Thyroidal secretion contains iodine in an organic combination described as thyroiodin by Baumann; so that the action of iodine in these cases is probably supplemental, like that of thyroid extract. Thus, potassium iodide 5 to 10 gr., or tincture of iodine 2 min., may be given three times a day. Hydrofluoric acid has been recommended by Woakes, who advised that 10 min. of $\frac{1}{2}$ per cent solution of the re-distilled fluoric acid in an ounce of water should be given twice a day, and the dose gradually increased.

In the simple form of parenchymatous goitre, the application of a blister, by painting the skin over the goitre with liquor epispasticus (B.P.), is often useful. In most cases, however, counter-irritation by the inunction of the red iodide of mercury ointment (1-25) is more suitable. Sometimes this ointment is too strong; it should then be used from a quarter to half the usual strength, that is to say, 5 to 10 gr. red iodide of mercury to 1 oz. benzoated lard, applied in small quantity each night, or even every other night. Tinct. iodi mitis (B.P.), iodine ointment, or a mixture of one part of it with two of potassium iodide ointment, may be applied instead. The efficiency of the red iodide of mercury ointment is increased by exposing the skin to the rays of the sun after its application; especially is this so in a tropical country, such as India. It has been suggested that the efficacy of this treatment may be due to the greater ease with which heat, and possibly other rays of the sun, pass through the skin after treatment with preparations of iodine. The powerful action of x rays in reducing the size of the lymphatic glands in lymphadenoma, and of the spleen in splenomedullary leukaemia, gave rise to the hope that a similar result might be attained in goitre. So far, however, the use of x rays and of radium has not fulfilled these expectations.

At one time injections of iodine into the goitre were employed, it being assumed that this direct introduction of the iodine into the substance of the gland would be more efficient than the other modes of administration. It is to be hoped, however, that this treatment has now been finally abandoned; it is dangerous and uncertain, no fewer than sixteen cases in which death had occurred in consequence of the injections having been collected by Heymann. Sir Victor Horsley has shown by experiment that death in such cases is due to the iodine being injected directly into a large blood-vessel, an accident which it is difficult to avoid on all occasions in the case of such a vascular stricture as a goitre.

In goitres in which adenomata or cysts are present, some diminution in size may follow a course of thyroid treatment, not of course owing to a decrease in the size of the adenomata or cysts themselves, but as a result of atrophic changes in the gland substance in which they are embedded. In such cases the operation for removal of an adenoma or cyst is simplified by a previous course of treatment with thyroid extract. (See also GOITRE, SURGICAL TREATMENT.)

George R. Murray.

GOITRE (Surgical Treatment).—Certain diseases of the thyroid body can be dealt with only by operation, while other diseases are susceptible to medical treatment—which again may sometimes need to be supplemented by operation. It is therefore necessary that a clear conception should be

obtained of what precisely can be attained by operative treatment, and of how that treatment produces its effect.

THE SCOPE OF OPERATIVE TREATMENT.

The following is a list of the various modifications in thyroid conditions which can be effected by operation. Used with a knowledge of the selection of suitable individual cases, the list will serve as an enumeration of the *indications for operative treatment*.

1. The relief of deformity due to large but symptomless goitres.
2. The relief of local symptoms due to pressure on structures adjacent to the thyroid.
3. The removal of localized foci of disease which, though possibly symptomless, would by their continued growth ultimately cause serious symptoms. Such localized foci of disease include :—
 - a. Localized encapsuled masses of colloid degeneration, single or multiple, cystic or solid, and usually described clinically as “thyroid adenomata.”
 - b. True adenoma of the thyroid—a benign glandular tumour.
 - c. Malignant tumours, sarcoma or carcinoma, but usually the latter.
4. The relief of hyperthyroidism accompanying disease—usually localized—of the gland.

5. The control of generalized diseases of the gland substance—viz., parenchymatous (colloid) degeneration, and Graves’s disease.

6. The relief of hypothyroidism by thyroid grafting.

Some comment on each of these classes is necessary.

1. **Deformity.**—Very large goitres, mainly or wholly cystic as a rule, and occurring in middle-aged or elderly persons, should be removed even if there is no other indication than the very repulsive deformity. The operation under these circumstances is almost always easy and safe. If, however, there is any evidence of hypothyroidism, the operation should not be advised unless it is clear that the goitre contains no functional thyroid tissue, as for example where it is entirely cystic.

2. **Local Pressure Symptoms.**—*Pressure on the veins* at the root of the neck or in the thorax is common, and may cause distention of the veins above the disease, cyanosis of the face, dizziness, and headaches. Some patients seem to be especially sensitive to slight degrees of venous congestion of the brain and meninges, and in them the headaches are severe.

Pressure on nerves is relatively common. Malignant disease tends to involve the recurrent laryngeal early and the sympathetic later. In advanced inoperable malignant disease the vagus and the roots of the brachial plexus are also affected. The only nerve affected by non-malignant conditions is the recurrent. It is therefore a mistake, in the absence of other signs, to suppose that recurrent paralysis is conclusive, or even very strong, evidence of malignant disease.

Pressure on the visceral structures of the neck (trachea and œsophagus) is very common, and most important. Lateral compression of the trachea is usual. If the goitre is unilateral, the trachea is in addition displaced to the opposite side, sometimes to such an extent that the displaced larynx may be mistaken for an enlarged gland or another tumour. When the goitre is placed far back, or in the thorax, severe dyspnoea may suddenly come on in a patient previously supposed to be quite well. Usually, however, some shortness of breath is noticed by the patient from an early period. Intrathoracic goitre pressing on the trachea, and possibly even on one or other main bronchus, causes a condition which may be regarded and tolerated by the patient as “chronic asthma.” There may be little or no goitre showing in

the neck, though the true state of affairs is at once disclosed by a radiogram of the thorax.

Pressure on the œsophagus, as might be expected, is not commonly a cause of definite obstruction, since unless the goitre be situated in the middle line and behind the sternum, anteroposterior pressure is not marked. A general discomfort and stiffness in swallowing is often complained of, from limitation of the vertical movements of the trachea which accompany the act. In malignant disease this fixation becomes very marked, and ultimately actual obstruction is common.

Local pressure symptoms of any kind may generally be regarded as an absolute indication for operation if the condition is such as to be amenable to operative treatment. The conditions usually calling for treatment under this indication are localized colloid masses, cervical or intrathoracic; true adenomata; and early malignant disease.

3. Thyroid "Tumours."—The term tumour is used here in a clinical sense, and includes some conditions which certainly are not true neoplasms, but which are still often described as adenomata.

a. The localized, and more or less distinctly encapsuled, colloid mass is undoubtedly the commonest of the three main varieties of localized thyroid swelling already mentioned above.

b. True adenoma of the thyroid, that is, a benign epithelial neoplasm, is a comparatively rare tumour. There is usually difficulty in distinguishing it from the carcinomata, and it occurs either as a solid, firm tumour consisting of alveoli filled with cells, or as a cystic tumour with intracystic growths.

c. Malignant disease of the thyroid is not very uncommon. It is not possible here to enter upon the very numerous histological forms in which the disease appears. In the great majority of cases it is a carcinoma of some kind. Sarcoma is comparatively rare. Carcinoma affects the glands of the posterior triangle early, so that a gland operation is always necessary in the treatment. The disease appears as a hard localized mass in the substance of the gland, and a certain diagnosis can scarcely ever be made in operable cases, and should not be expected. The sinister reputation of carcinoma of the thyroid is probably to a great extent due to the fact that it is usually regarded as capable of diagnosis before operation.

INDICATIONS FOR TREATMENT.—*A localized mass in the thyroid should invariably be excised, whether it is causing symptoms or not.* The chief reason why this principle can be laid down so dogmatically is that such a swelling will almost invariably increase in size, and ultimately produce symptoms at a time when it is more difficult to remove. It must be remembered, moreover, that malignant disease also begins as such a localized symptomless mass, and, at a time when it still remains curable by operation, cannot be distinguished clinically from a simple adenoma or a localized colloid tumour. Malignant disease may be suspected when a localized mass which has remained quiescent in the thyroid of a middle-aged person for some time, possibly years, begins to increase in size and hardness, and to lose its well-defined outline. In the later stages, when nerve-involvement is present and the thyroid gland itself begins to be fixed to surrounding parts, the diagnosis becomes more sure, but the treatment incomparably less hopeful. Involvement of the cervical lymph glands, contrary to what is frequently thought, is not a very unfavourable complication in malignant disease, provided an adequate gland dissection of the modern type is carried out. Experience also shows that a total extirpation of the thyroid gland is not essential for the cure of malignant disease. In rare cases, it is true, multiple nodules of carcinoma are found in the gland; but such an occurrence is so uncommon as not to justify the very serious operation

of total thyroidectomy as a routine treatment of malignant disease. In elderly or old patients the operation may produce no grave disturbance, and may sometimes be advisable; but carcinoma is not uncommon at about the age of forty, and in such patients it is usually very difficult, if not impossible, to establish satisfactory compensation by thyroid feeding or thyroid grafting.

A clinical picture closely resembling that of malignant disease of the thyroid is produced by certain cases of carcinoma of the œsophagus in which the disease has spread at an early period into the lateral lobe and produced a firm swelling of the thyroid, gradually extending from behind forward. In such cases recurrent paralysis and thyroid swelling are early signs, while dysphagia may be late or absent. It is a very serious error to operate on a case of this kind, as the operation cannot be completed, and an œsophageal fistula, with infection of the tissues of the neck, is almost certain to result.

In advanced colloid degeneration, a part or even the whole of the gland may be occupied by more or less distinct rounded masses, which are sometimes described as multiple adenomata. In such cases operation should always be advised. It may not, however, be possible to remove all the swellings by an operation of less extent than a total thyroidectomy. This is rarely, if ever, justifiable. The best course is to remove the lobe most affected, and to enucleate such other nodules of disease as are accessible.

4. The Relief of Hyperthyroidism.—Certain cases of thyroid disease (almost always colloid degeneration) develop a peculiar group of symptoms, including tachycardia, palpitation, tremor, nervousness, wasting, and general weakness. These symptoms resemble those produced by the administration of thyroid extract, and are regarded as being due to the thyroid secretion reaching the patient's blood in excessive amount, though of normal quality. These cases have sometimes been regarded as larval or incomplete forms of Graves's disease. There can be little doubt that this conception is incorrect. The clinical condition is a well marked one, and in the great majority of cases is easily distinguishable from Graves's disease. The thyroid contains one or more rounded masses of colloid degeneration, well defined and easily palpable, in the substance of the gland, and there is little evidence of the local arterial dilatation and excessive pulsation so characteristic of the generally-enlarged gland of Graves's disease. Moreover, the symptoms do not include the more serious and characteristic manifestations of the latter, such as exophthalmos, progressive course, and liability to acute attacks with fever, vomiting, and diarrhœa. It must be admitted that an exact differentiation between the two conditions is difficult in a description, because isolated symptoms not usually present in hyperthyroidism may occasionally appear in it and challenge the validity of an absolute rule. Nevertheless, those familiar with the two conditions will find no difficulty in making the distinction in the great majority of cases. It is useful to remember that mild cases of Graves's disease are usually quite as characteristic as severe ones, and do not approximate to the type of hyperthyroidism; and that exophthalmos, although opinions to the contrary are frequently expressed, is almost invariably present in Graves's disease. The diagnosis of these two conditions is extremely important, and must always be carefully considered, because their amenability to treatment is so different. Hyperthyroidism due to a single localized colloid mass can almost certainly be cured by the removal of the latter by an operation easy to carry out and free from serious danger. In some comparatively rare cases hyperthyroidism occurs as a complication of widespread and active colloid degeneration. In these cases, and especially in relatively young patients, although relief follows partial resection of the enlarged gland, the swelling and the toxic symptoms are apt

to recur. Under such circumstances, a second partial thyroidectomy may be undertaken; but care should be taken not to reduce the residue of the gland too much.

5. The Control of Generalized Disease of the Gland.—There are two diseases of the gland which tend to become generalized throughout its substance—parenchymatous (colloid) goitre, and exophthalmic goitre (Graves's disease). The course of both can be directly influenced by surgical treatment.

Parenchymatous Goitre.—In its earliest stages this has some of the features of a physiological hypertrophy, and usually subsides spontaneously or as the result of medical treatment. Supposing, however, such treatment to be ineffective, there is a further resource in operation. The progress of the disease can usually be arrested, and subsidence brought about, by a partial removal of the gland. If any harder nodule can be felt, the part of the gland chosen for removal should be that containing it. It is clearly to be understood that the object of the operation is to check the progress of the disease, so that the indications for it are independent of the existence of symptoms, and are based on the persistence of a large parenchymatous goitre in spite of medical treatment. It is not known how the operation produces its effect, but it is remarkable how large a goitre will rapidly disappear after the excision of a comparatively small fraction of its substance.

Exophthalmic Goitre.—In attempting to define the scope of operative treatment in exophthalmic goitre, it is necessary to review some of the pronounced features of the disease. There can nowadays be little doubt that the primary cause of all the symptoms is the abnormality of the thyroid. The essential change in the gland is hyperplastic in type, but the newly-formed tissue differs strikingly in appearance from normal thyroid tissue, and produces a secretion which is not only excessive in amount but also abnormal in quality and highly toxic. It is important to remember that, side by side with the hyperplastic changes, destructive changes are going on in scattered foci throughout the gland, so that considerable tracts of the gland substance are ultimately replaced by fibroid tissue. Variations in these destructive changes are the chief differences to be seen in sections from goitres from different cases and of different degrees of enlargement.

The disease is capable of spontaneous recovery, usually after a course of several years. Recovery generally leaves the gland abnormally fibrotic, and sometimes permanently enlarged and hard.

A considerable number of patients—perhaps about 10 per cent—die of the disease; of those who survive, all are totally incapacitated during the acute attacks, and some throughout the whole course; of those in whom the disease becomes quiescent, many will have sustained damage to the heart; while, finally, recovery may be accompanied by the appearance of hypothyroidism or definite myxœdema. It is not unusual in long-standing cases to find the symptoms of early myxœdema side by side with those of Graves's disease.

It follows from the foregoing that, even if the mortality accompanying operative treatment were not much less than that of the untreated disease, such treatment would have a great deal to recommend it if it were efficient in arresting so distressing and burdensome a malady. Though doubtless many lives have been saved by the operation—and the operative mortality of the most experienced surgeons is about 5 per cent or less—it will probably not be until operation becomes a routine treatment in early cases that it will effect any gross reduction in the total death-rate from the disease.

Medical treatment is admittedly directed to the relief of symptoms, and cannot be regarded as having any effect on the duration of the disease.

The only methods of acting directly on the thyroid are radio-therapy and operation.

The disadvantage of *x*-ray treatment seems to be that its effect, when any is produced, is purely destructive, and not selective for the diseased process. Consequently there is a certain risk of carrying the action too far and producing thyroid insufficiency.

The operative measures which may be used are ligature of vessels and partial thyroidectomy. Ligature of vessels is an easy operation, and should be used chiefly as a preliminary to partial thyroidectomy in severe cases. The superior thyroid pedicle on one or both sides should alone be tied, as access to the inferior thyroid artery is difficult and not much less severe than partial thyroidectomy. Moreover, the inferior thyroid veins are not tied at the same time, and it is quite probable that occlusion of veins is an important factor in the success of the ligature operation. Partial thyroidectomy, usually of one lobe, is undoubtedly the most efficient measure, and should be the operation of choice. It probably acts in two ways: first, by the removal of diseased tissue it diminishes the dose of toxic secretion being absorbed, and so produces an immediate improvement; second, the incision of and relief of tension in the gland directly affects the disease process itself, and so produces a more lasting effect.

As to results, it may be said that all patients who survive the operation show some improvement; that in really early cases, where the symptoms have not fully developed and the diagnosis is made chiefly on the ocular and thyroid physical signs, the improvement in almost all cases is complete and permanent; that in moderate and severe cases the results are more capricious, but that in at least 50 per cent the results are extremely satisfactory, though complete restoration to the normal is not infrequently prevented by the persistence of an isolated symptom such as exophthalmos. The most striking results are seen in the severest cases. Such patients may be restored from a state of bed-ridden invalidism to active life, though they usually retain some fixed residual symptoms. Of the moderate and severe cases, a considerable number—perhaps as many as 25 per cent—develop, after a period of excellent health of six months to two years, a recurrence of thyroid swelling and a return of symptoms. Such relapses usually yield readily to a further partial thyroidectomy.

With regard to the selection of cases for operative treatment, but few definite rules can be laid down. It is not possible to recognize cases clinically which are especially likely to give satisfactory results. There can be little doubt that the earlier the case the more likely is a single operation to be curative. The chief object of selection must be to avoid cases in which the operation is likely to be particularly dangerous. No case should be operated on during an acute exacerbation; vomiting, diarrhoea, and fever of any considerable height, should be absolute contra-indications for the time. The patient's mental state is most important; if she is anxious to get well, and looks forward to the operation without fear, she is much less likely to suffer severely during it and afterwards than if she is much agitated by the thought of it and the preparations for it. It is highly desirable to keep the patient in bed for a week or two before the operation.

Graves's disease usually attacks a previously healthy thyroid, but sometimes it occurs in a gland already containing colloid tumours. Such cases do not sensibly differ as to course and prognosis from the ordinary type, and must be carefully distinguished from those of colloid goitre with mere hyperthyroidism.

6. Thyroid Grafting.—This procedure has not fulfilled the hopes of its originators. It may be considered in cases of cretinism, myxœdema, or cachexia

strumipriva in which there is some obstacle to securing regular administration of thyroid extract, or there is exceptional difficulty in giving a satisfactory dose without producing toxic symptoms. Grafts are usually implanted in one of three situations, the subperitoneal tissue, the cancellous medulla of a long bone, or the spleen. In the last-named the results are said to be most satisfactory, but the operation is not without danger. Subperitoneal grafting has the advantage of simplicity, and is not very much less satisfactory than the other methods. None but perfectly normal thyroid tissue should be used; two or three masses of about a cubic centimeter each may be implanted. The effect generally is rather that of a large dose of thyroid gradually absorbed, than of the establishment of a permanent source of normal secretion.

GENERAL FEATURES OF THYROID OPERATIONS.

No detailed description of operations will be attempted here, but it is desirable to indicate in broad outline the principles which must be followed in such procedures.

Anæsthesia.—Ether given by the open method, and following an injection of scopolamine, morphine, and atropine, is undoubtedly the most generally applicable of all anæsthetics for thyroid cases. Anæsthesia should be induced while the patient is in bed.

Local anæsthesia, especially if preceded by the injection of scopolamine and morphine, is very often useful and satisfactory. It is particularly applicable to cases of very well defined encapsuled tumours which can be enucleated, especially cysts. It cannot be so thoroughly relied on for hemithyroidectomy, especially if the goitre is large. For operations in Graves's disease it is on the whole decidedly less valuable than ether.

Incisions.—The incision of choice in all ordinary cases should be the transverse collar-cut of Kocher following exactly the natural flexures of the skin. The only disadvantage of this incision is the imperfect access it gives to the upper pole of the lateral lobe. If the ends of the incision be much upturned to overcome this defect, the visibility of the scar is greatly increased, and the advantage of the method is lost. Where freedom of access is of great importance, as in dealing with exophthalmic goitre or malignant disease, cosmetic considerations must be disregarded. In Graves's disease, an incision along the whole length of the lobe to be removed, and about the anterior border of the sternomastoid, is very satisfactory. In malignant disease, a long transverse incision is often desirable, extending even to the anterior edge of the trapezius on the side of the disease. The sternomastoid is divided near the sternum, and the glands of the posterior triangle removed with the affected thyroid lobe. A similar though shorter incision, with or without division of the sternomastoid, is very useful for the removal of intrathoracic goitres.

Drainage.—Drainage by a tube for twenty-four hours should almost always be practised. Its sole purpose is to prevent the wound becoming distended with blood-clot, a complication which prolongs the discomfort of convalescence, and may delay healing. If continued for more than twenty-four hours, a mucoid discharge of thyroid juice is apt to persist for several days and cause some risk of infection. Even the large cavity left by the removal of an intrathoracic goitre should not be drained for more than twenty-four hours. Doubtless it usually fills up with blood, but primary union is the rule.

The Operation of Enucleation and its Modifications.—With the recognition that most localized thyroid swellings are not true adenomata, the practice of formal enucleation has somewhat declined. It is most satisfactory for the removal of cysts. The gland is exposed and incised until the wall of the cyst is met with, and then the latter is enucleated. If the cyst is large there

can be no objection to puncturing it, as that renders removal quite easy through a comparatively small incision. Almost always there is rather obstinate bleeding from the cavity left in the thyroid; in stopping this, the nearness of the recurrent nerve to the postero-interior aspect of the gland should be remembered.

In most cases it will be found convenient to combine partial enucleation with resection or excision of the part of the gland to which the tumour is most adherent. There can be no advantage in persisting in carrying out a formal enucleation in the face of serious adhesion and hæmorrhage, when a partial excision is so much easier.

Hemithyroidectomy.—This is the operation of choice for extensive colloid disease, for exophthalmic goitre, and for malignant disease. Except in the case of the last-named, it is generally best to leave a small part of the postero-internal border of the lobe to guarantee the safety of the recurrent nerve. In colloid disease this is not desirable if there is a process of the gland extending inwards between the trachea and œsophagus.

After the infrahyoid muscles have been split longitudinally, the superior thyroid pedicle is defined, divided, and ligatured. The lobe can usually be dislocated into the wound, and the subsequent dissection made easier. It is then best to deal with the inferior thyroid pedicle, cutting through the gland substance rather than dividing the vessels outside the capsule. The gland is always firmly fixed by dense fibrous tissue passing between its inner surface at the junction of lobe and isthmus to the side of the cricoid. In cutting through this ligament, the risk of injuring the trachea must be remembered.

In dealing with exophthalmic goitre, every effort should be made to prevent the operation being either long or bloody. Two precautions are necessary for this—a free incision to give complete exposure of the lobe, and the definition and securing of all vessels before they are divided. An attempt to do the operation through a restricted incision, and by methods which would be perfectly adequate in dealing with a colloid goitre, can only lead to unnecessary or even uncontrollable hæmorrhage, and at the least, undue delay.

Operations for Intrathoracic Goitre.—It is desirable to lay stress on the fact that, formidable as they appear, cases of intrathoracic goitre are almost always operable. No patient suffering from this very distressing condition should be left without an attempt being made at relief. The operation, it is true, demands some special knowledge and a certain amount of fortitude from the surgeon, but when successful its results are brilliantly satisfactory. A large horizontal incision should be made, and it is often well to divide the sternomastoid. If the intrathoracic mass is attached to one of the lateral lobes, this latter should be freed from its pedicles and the isthmus, and can be used to make traction on the intrathoracic mass. The tumour is very rarely adherent within the chest, and can as a rule be readily separated by the finger, so that serious bleeding is quite unusual. If removal intact is impossible, the mass may be extracted piecemeal with a large scoop—a much less satisfactory procedure, as prolonged drainage may be necessary.

After-treatment.—After the operation, the patient should be propped up in the sitting position, with her head slightly bent to allow the wound surfaces to fall together. In all ordinary cases convalescence is rapid after the first forty-eight hours. The tube should be removed on the first day, the stitches on the seventh or eighth, and the patient allowed to get up about the tenth. In cases of Graves's disease there is always a considerable exacerbation of the symptoms immediately after the operation. Restlessness, fever, palpitation, hurried respiration, and profuse secretion of pharyngeal and bronchial mucus, are the chief symptoms. If they have not become severe by the end of the

first twenty-four hours the outlook is good, and they usually subside during the next day or two. Morphia should be given at the first onset of serious restlessness, and combined with atropine if there is much mucous secretion. Every effort should be made to reassure the patient and to prevent her giving way to alarm, which always aggravates symptoms. The temperature is always raised for the first few days, and may remain between 100° and 101° for as long as ten days. Such fever need give rise to no anxiety as to the asepis of the wound.

Wilfred Trotter.

GONORRHŒA.—The efficient treatment of gonorrhœa is quite as important as that of syphilis; and, as in the latter disease the principal object of treatment is to modify the intensity of the syphilitic virus as early as possible, and thus prevent the appearance of tertiary lesions, so in gonorrhœa our aim should be to minimize its ill-effects, and to prevent the supervention of complications. Gonorrhœa is an infective disease due to a specific micro-organism, the gonococcus, which is capable of rapid extension and proliferation, and which, unless dealt with at the earliest possible opportunity, will ultimately involve the whole of the urethral mucous membrane. Not only does it affect the urethra locally, but ultimately it may give rise to a general blood infection, which is the cause of many of the later phenomena of the disease. The majority of the serious complications of this disease do not present themselves until the prostatic portion of the urethra is involved; consequently the primary aim of treatment is to prevent the gonococcus from reaching that part of the urethral mucous membrane.

The one agent which is destructive to the gonococcus is nitrate of silver, but even in weak solutions this sets up such an irritation of the urethral mucous membrane as to preclude its use. However, of late years various modifications of nitrate of silver have been devised which, whilst destructive to the gonococcus, are only slightly irritating to the urethral mucous membrane, and are capable of penetrating into its deeper layers. Amongst these may be mentioned protargol, nargol, argyrol, argentamin, albargin, ichthargan, and argonin, of which the first two have yielded the best results in the experience of the writer. Solutions of these substances of 1 to 2 per cent strength are applied to the urethral mucous membrane by injections introduced by means of a urethral syringe in the following manner: The patient should first empty his bladder, and should introduce the nozzle of the urethral syringe into the meatus, and inject a sufficient quantity of the solution to distend the urethra gently (about 2 to 3 dr.). The syringe is then withdrawn, and the solution is retained in the urethra for a gradually increasing period of time, starting at two minutes, but ultimately extending to twenty minutes, in proportion to the severity of the case and the tolerance of the individual; the injections should be used three or four times daily. The injections may at first cause some increase in the amount of the discharge and of the ardor urinæ, but they will shortly modify the purulency of the discharge, and will be productive of little if any pain. In exceptionally acute cases, owing to the extreme tumefaction of the mucous membrane and to the intense pain, it may be necessary to postpone the use of injections for a few days.

If encountered sufficiently early, the abortive treatment may be applied: A solution of eucaïne and adrenalin is injected into the anterior urethra, and the urethroscope tube is introduced as far as the bulb. All discharge and moisture having been absorbed by pledgets of cotton-wool fixed on a holder, the whole of the anterior urethra is thoroughly swabbed out with a solution of protargol, 5 to 10 per cent, and subsequently mild antiseptic irrigations are employed for a few days.

Acute gonorrhœa may also be treated by Bier's method of passive venous congestion : a glass cylinder, fitted at the open end with a rubber diaphragm, adapts itself accurately to the root of the penis, and a vacuum in the cylinder is created by means of a small pump.

Acute gonorrhœa has recently been treated by the application of heat, for the reason that the gonococcus is said to be destroyed by exposure to a temperature of 104° F. One method of applying the heat is by means of a double catheter, the inner compartment of which is connected with an irrigator by means of a rubber tube, whilst an outer provides an outlet for the injected water. The instrument is introduced into the bladder, and water is conveyed to it from the irrigator, first at a temperature of 114° F., and subsequently increased to 125° F. ; the treatment is continued for thirty minutes. The heat may also be applied by means of gum elastic or metal bougies heated by an electric resistance coil enclosed within them, and the temperature is regulated by means of a thermometer ; the temperature may be raised to 150° F., maintained for fifteen minutes, and the process may be repeated two or three times a week. In eleven acute cases the gonococci disappeared on the fifth day.

Formerly, the treatment of the early stage of gonorrhœa was simply a palliative one, by means of alkalies and sedatives, and consequently the gonococcus was given a free scope, and was rather encouraged to make its way to the posterior urethra ; but now that the pathology of the disease is better understood, the treatment is commenced at the earliest possible opportunity, with the view of repelling and exterminating the invading germ. During the decline of the disease, the injections of the nitrate of silver compounds should be continued until on careful microscopical examination no gonococci can be discovered in the discharge. Then recourse may be had to astringent injections such as a solution of the sulphate, permanganate, sulphocarbolate, or chloride of zinc, and this treatment should be continued for a week after the final disappearance of the discharge. In obstinate cases an injection of the four sulphates may be tried, e.g. :—

R	Zinci Sulphatis	Cupri Sulphatis	āā gr x
	Aluminis Sulphatis	Aquam Destillatam	ad ʒ viij
	Ferri Sulphatis		

To be diluted with two parts of water, and the strength gradually increased.

Or,

R	Zinci Sulphocarbolaris	ʒ ss	Glycerini	ʒ ss
	Hydrargyri Perchloridi	gr ½	Aquam	ad ʒ viij
	Acidi Carbolici	gr x		

As a substitute for injections, treatment by irrigation of the urethra with weak solution of permanganate of potash or ichthyol solution has been recommended, and as a modification of this, Janet's treatment must be mentioned. It consists in the introduction, under pressure, of antiseptic or astringent solutions through the urethra into the bladder, without the assistance of a catheter. In Janet's original method permanganate of potash solutions were employed, but all the modifications of nitrate of silver already alluded to may be utilized, as also solutions of hydrogen perchloride, bismuth subnitrate, sodium salicylate, or hydrogen peroxide. As a preliminary to the irrigation treatment, it is recommended that a dose of atropine should be administered by means of a suppository containing gr. $\frac{1}{30}$ to $\frac{1}{20}$, the object being to put the affected organs at rest by preventing the automatic and reflex muscular actions of the sexual organs, which are under the control of the hypogastric plexus.

At the commencement of the attack, a brisk purgative should be administered, and subsequently a saline aperient may be taken every other morning. As aids to the local treatment, the so-called balsamic remedies, copaiba, cubeba,

sandalwood oil, thyresol or methyl ether of sandalwood, or gonosan, should be given, preferably in the form of capsules, but should not be persevered with if they give rise to any disturbance of the digestive functions, or if they set up a dermatitis. A light diet is an essential factor in the treatment, and abstinence from all alcoholic drink, from highly seasoned dishes, shell-fish, asparagus, and coffee should be enjoined; at the same time any sexual excitement must be absolutely prohibited, and any violent exercise, especially riding, should be forbidden. Large quantities of bland, demulcent fluid, such as barley-water, will, by diluting the urine, considerably lessen the pain experienced on micturition. Diuretics and vesical disinfectants such as hexamine, piperazin, and helmitol are also valuable adjuncts to treatment of the disease in all its stages.

A certain proportion of cases will yield to treatment carried out on the above lines, but not infrequently the discharge persists in spite of all efforts to check its progress, and the condition of chronic gonorrhœa, or gleet, ensues. Here the discharge may proceed from the anterior part of the urethra, and is then caused by involvement of some of the urethral follicles, by stricture of the urethra, or by granular patches or papillomata of the urethral mucous membrane. If the cause is situated anteriorly to the compressor urethræ muscle, it can be discovered by urethroscopic examination, and will usually require treatment applied locally down the urethroscopic tube; thus any granular patches and papillomata, or the orifices of any of the urethral lacunæ which might be affected, may be touched with a solution of nitrate of silver (5 to 20 gr. to 1 oz. water), and if any constriction of the urethra or any peri-urethral thickening is present, it should be treated by the passage of bougies in increasing sizes up to 25 or 28 F. If the gonococcus has reached the prostatic urethra, a region inaccessible to the ordinary injection, it is advisable to apply a few drops of the nitrate of silver solutions by means of a Guyon's syringe.

In dealing with the treatment of gonorrhœa, some allusion must be made to vaccino-therapy, which is reported to have been attended with considerable success in the hands of bacteriologists; in my experience it is useless in the early stages of the disease, and is only indicated when the gonococcus is encapsled and shut off from local applications, as in cases of arthritis, prostatitis, vesiculitis, endometritis, and salpingitis. The same criticism applies to gonorrhœa phylacogen, of which favourable reports have been received in all stages of the disease, though personally I cannot say that I have ever seen any marked improvement caused by this treatment in any phase or complication of gonorrhœa.

COMPLICATIONS.

The complications of gonorrhœa are manifold, and often of vital importance, but the majority of them do not occur until the prostatic portion of the urethra has been infected.

Gonorrhœa of the anterior urethra.—This may be complicated by: Acute lymphangitis, folliculitis, peri-urethral abscess, inflammation and suppuration of Cowper's glands, and chordee.

Lymphangitis.—In acute gonorrhœa the lymphatics of the penis and the inguinal glands may be the seat of inflammatory changes, causing phimosis, a cord-like enlargement of the dorsal lymphatics of the penis, and swelling and tenderness of the inguinal glands. This condition seldom proceeds as far as suppuration, and usually yields to treatment by rest, purgatives, and hot fomentations.

Gonorrhœal Folliculitis.—In this condition the glands of Littre in the floor of the urethra are invaded by the gonococcus and form small hard nodules

easily displayed by urethroscopic examination, and palpable to the touch on the under surface of the corpus spongiosum. They may be treated by the passage of a large metal instrument on which they can be massaged, or may be opened by means of a sharp wire passed down the urethroscope.

Peri-Urethral Abscess may occur in connection with the urethral follicles, and is met with at any portion of the urethra from the meatus to the bulb; the pus may make its way into the urethra, or towards the skin, and its escape externally is preferable to its bursting into the urethra, since in the latter case recurrence is frequent; these abscesses should be opened by skin incision directly fluctuation can be detected.

Abscess of Cowper's Glands will form a perineal swelling which will also require to be opened and drained.

Chordee.—The pain of chordee may be relieved by the application of cold, or simply by the act of micturition, and the tendency to erection may be treated by opium and belladonna suppositories, or by a mixture of bromide of sodium and extractum salicis nigri fluidum.

Gonorrhœa of the posterior urethra. The following complications may be met with: Acute and chronic prostatitis and prostatic abscess, epididymitis and orchitis, seminal vesiculitis, and cystitis, possibly extending up the ureter and giving rise to pyelitis.

Acute Prostatitis.—The pain may be relieved by suppositories of opium and belladonna, by immersing the patient in a hot hip-bath, by leeches to the perineum, and if an abscess has formed, it may be opened by a perineal incision. *Chronic Prostatitis* is a common cause of chronic urethral discharge, and is a condition requiring prolonged treatment; from its chronicity and its tendency to recurrence it is accompanied by considerable depression, both mental and bodily, and is a fruitful cause of sexual hypochondriasis. The treatment consists of instillations into the affected portion of the urethra of a few drops of the nitrate of silver solutions in the strength of 5 gr., 10 gr., or 20 gr. to 1 oz.; suppositories of opium, belladonna, and ichthyol, cold hip-baths, cold rectal and perineal douches, careful regulation of the bowels, restricted diet, and the avoidance of violent exercise and sexual excitement. In obstinate cases massage of the prostate gland per rectum, followed by instillations of a solution of nitrate of silver, is often followed by beneficial results.

Epididymitis is one of the most frequent complications of gonorrhœa, and at the same time one of the greatest gravity, since it is liable to cause sterility by obliterating the tube of the epididymis and so causing azoospermia. The essential point in the treatment is to suspend the testicles, and at the same time to apply heat and pressure. This is best effected by a "Jullien's" suspensory bandage, the bag of which is large and made of thick waterproof tissue; this is evenly padded with cotton-wool and applied to the scrotum, and exerts pressure on the testicles when the lateral tapes are adjusted; it is retained in position by abdominal and perineal straps. The effect of this is to give almost instantaneous relief from the severe pain which is inseparable from this condition, and also to promote the absorption of the inflammatory effusion. At the same time, the prostatic urethra should be treated by small instillations of nitrate of silver solutions, with the view of preventing the spread of the disease to the other testicle. As adjuncts to the local treatment, rest, light diet, and aperients may be prescribed.

Seminal Vesiculitis, if acute, should be treated by rest, cold or hot rectal irrigations, leeches to the perineum, and opium and belladonna suppositories; if an abscess forms in the vesicles, a perineal incision should be made, and the abscess approached and evacuated by dissection between the bladder and rectum. If chronic, the distended vesicles should be emptied of their contents

by massage with the forefinger through the rectum ; this should be carried out once or twice weekly, together with instillations of nitrate of silver solutions. Catheterization of the common ejaculatory ducts has been carried out by means of the passage of a large urethroscopic tube, through which a fine catheter has been introduced into the orifices of the ducts ; the object of the treatment is not to irrigate the seminal vesicles, but to break down an obstruction to the escape of the secretion therefrom, and to relieve the condition of vesicular retention. Vesiculectomy has also been practised, the vesicles being removed by perineal, ischio-rectal, or inguinal incision.

Cystitis is another complication frequently met with in posterior gonorrhœa, but it is usually limited to the region of the neck of the bladder, and is chronic in degree. In this condition rest is necessary, the diet should be light, and large quantities of barley-water should be administered ; to counteract the vesical spasm and consequent frequency of micturition, opium and belladonna suppositories should be introduced, and the patient should be placed in a hot hip-bath. A very valuable remedy in cystitis is helmitol or anhydromethylene citrate of hexamethylenetetramine ; this, in consequence of the ample liberation of formaldehyde, acts as a powerful disinfectant upon the urine, and also imparts to it an acid reaction ; it should be given in doses of 10 to 15 gr., three or four times a day, administered with large quantities of water or soda-water. Gentle irrigation of the bladder with warm solutions of boracic acid, salicylate of soda, or nitrate of silver and its modifications, is indicated in the subacute and chronic forms of cystitis.

Gonorrhœal Rheumatism is another complication of a posterior gonorrhœa, and is caused by a generalized infection of the blood by means of the gonorrhœal toxin ; it may affect the joints or peri-articular structures, the sheaths of tendons, fasciæ, and bursæ. Treatment should be directed firstly towards the urethral affection, and instillations of nitrate of silver solutions may be made into the prostatic or any other portion of the urethra affected. The joints or other structures involved in the process may first be treated with cold applications by means of an ice-bag, spirit lotion, or Leiter's tubes, and must be kept at complete rest ; later, counter-irritants may be prescribed, such as iodine liniment, blistering, and the actual cautery ; pressure by means of Scott's dressing and strapping, or by elastic bandages, may relieve this condition, and also the hot-air bath and massage may be employed. In acute cases leeches may be applied, also Bier's passive congestion method, kataphoresis, and hot-air baths. If the affected joint is greatly distended, it may be necessary to relieve it by aspiration and by the injection of tincture of iodine or some weak astringent lotion. Internally, large doses of alkalies may be administered, or the salicylates of soda and quinine, iodides, salol, or acetyl-salicylic acid.* One condition which appears to predispose to these joint complications in gonorrhœa is seminal vesiculitis, and if this condition is discovered to be present by rectal examination, it should be treated on the lines already indicated.

Gonorrhœal Ophthalmia is caused by inoculation of the conjunctiva with gonorrhœal pus, and may be met with in adults and in newly-born children infected with pus from the maternal vagina ; its progress is characterized by its rapidity and destructiveness ; the condition is thus one calling for prompt and energetic measures. Locally, solutions of nitrate of silver 10 gr. to the ounce, of protargol, or of argyrol, should be applied daily to the whole conjunctival surface by means of a camel's-hair brush, and the superfluous lotion should be washed from the eye with warm water or weak boracic lotion. Any accumulation of discharge must be prevented by the frequent application of astringent and antiseptic lotions such as boric acid, alum, perchloride of mercury, or sulphate of zinc. Cold-water compresses will considerably relieve the pain, as also will

* Hastings has found autogenous vaccines to be of great service in gonorrhœal arthritis.—AMERICAN EDITOR.

the application of one or two leeches above the outer angle of the orbit. The greatest care must be taken to avoid inoculation of the sound eye, and this is best effected by securing a watch-glass over it with strips of strapping. The treatment internally should consist of a brisk purgative at the commencement, and later of tonics, anodynes, and even stimulants in cases where much bodily and mental depression is present. In ophthalmia neonatorum, local treatment with weaker nitrate of silver solutions and antiseptics is indicated, and its success and the recovery of the patient will depend mainly on the skill and assiduity with which the prescribed treatment is carried out by the nurse.

Gonorrhœal Iritis is an occasional complication of gonorrhœal rheumatism, and is characterized by its subsequent tendency to recurrence. Locally, atropine and cocaine lotion should be applied three or four times a day, and mercurial ointment with iodine and belladonna may be rubbed into the temporal region; internally, salicylate of soda, iodide of sodium or ammonium, acetyl-salicylic acid, or quinine will be productive of benefit.

In rare instances gonorrhœa is complicated by peritonitis, pericarditis, endocarditis, and spinal meningitis, the treatment of which should be carried out on general surgical and medical principles.

GONORRHŒA IN THE FEMALE.

In the female, gonorrhœa may primarily affect either the vagina, the vulva, or the urethra, whence it may spread to adjacent organs of importance.

Vaginal Gonorrhœa in the acute stage should be treated by vaginal douches of hot water if the patient can submit to them, and on the subsidence of the acute symptoms a vaginal speculum may be passed, and the vaginal mucous membrane may be thoroughly swabbed out with a strong solution of nitrate of silver, 10 gr. to the ounce, or with a 5 per cent solution of protargol or nargol, and after this a glycerin tampon be introduced. The more chronic forms of vaginal discharge may be treated by astringent injections given three or four times daily; the solutions usually employed are sulphate of zinc, sulphocarbonate of zinc, permanganate of zinc, chloride of zinc, and alum.

Gonorrhœal Vulvitis may be treated by hot-water applications at first, and subsequently by painting over the inflamed surface with a strong solution of nitrate of silver, 20 gr. to the ounce, after which the parts should be dressed with pledgets of lint soaked in lead and opium lotion.

Gonorrhœal Urethritis should first be treated by alkalies and hyoscyamus taken internally, and also large quantities of barley-water; if there be much pain and difficulty in micturition, immersion in a hot hip-bath, and the introduction of a few drops of cocaine solution into the urethra, will afford relief. On the subsidence of the acute stage, the balsamic remedies above mentioned may be prescribed internally, and the urethra may be painted over with a solution of nitrate of silver, 2 gr. to the ounce.

Abscess of Bartholin's Glands is a frequent complication of gonorrhœa in women, and should be treated by early incision and plugging the cavity with antiseptic gauze; if the abscess recurs, the whole of the gland should be dissected out.

Gonorrhœal Warts or vegetations may be met with in both sexes, but attain far greater magnitude in women than in men; as their progress appears to be encouraged by moisture, the principal indication for treatment is to keep the region dry by applying a dusting powder of starch, oxide of zinc, or savin powder. The more exuberant form of warts will require severer methods, such as the application of caustics, e.g., carbolic acid or acid nitrate of mercury, or removal with the knife or the thermo-cautery.

From the vagina the disease may extend up the cervix uteri to the body of

the uterus, thence along the Fallopian tubes to the ovaries, and possibly to the peritoneal cavity; but the treatment of these conditions belongs rather to gynecology than to genito-urinary surgery.

J. Ernest Lane.

GOUT.—No routine treatment can be adopted which is suitable to all cases of gout. The nutritional condition of the patient, his habits, surroundings, and mode of life, constitute factors that necessarily modify the treatment of individual cases; and with gout, as with so many other diseases, it will be found that each case requires separate study and frequently special treatment. Quite apart from the treatment of an attack, which is a comparatively simple and easy matter, must be considered the condition or conditions which led up to it. The gouty individual is one whose general metabolism is unstable, and this instability may be present in one or more of the great physiological systems—digestive, nervous, circulatory, etc. Which of these is primarily and mainly at fault should always be a question for patient investigation, and one must then endeavour to improve the metabolism of that system by suitable medicinal, dietetic, and hygienic measures.

The treatment of gout should aim at treating the following manifestations: (1) *The gouty paroxysm* in acute cases, and the relief of the pain as speedily as possible; (2) *The subacute or chronic condition*, and the prevention of recurrence; and (3) *The affected joints*, with the object of removing the uratic deposits and of preventing permanent deformity.

1. **Acute Gout.** *The Treatment of the Gouty Paroxysm.*—The limb should be placed in the horizontal position, or slightly elevated above the level of the body, and a cradle should be arranged to remove the weight of the bed-clothes off the affected part. To alleviate the severe pain in the joint, warm packs should be arranged round it, consisting of cotton-wool saturated with a soothing lotion, and then lightly covered with oiled silk. I have found the following lotion most useful in relieving the local pain:—

R Sodii Carbonatis	℥ij	Tincturæ Opii	℥iiss
Linimenti Belladonnæ (B.P.)	℥ij	Aquæ	q.s. ad ℥viii

A small portion of the lotion should be mixed with an equal quantity of hot water, and then poured on cotton-wool previously arranged round the joint. The pack should be changed every two hours. In connection with the acute paroxysm no attempt at local depletion—such as the application of leeches to the inflamed joint, blistering, or incisions—should on any account be made, owing to the great liability of thereby extending the inflammatory condition, and so producing subsequent ankylosis or deformity.

For the internal treatment, colchicum is one of the most valuable drugs we possess. It should be used especially for acute gout, and for subacute attacks supervening on chronic gout. If employed continuously, tolerance may be acquired, and then the drug ceases to act. At the commencement, a large dose, 30 to 40 min., of colchicum wine (B.P.) should be given, followed by a mixture containing in each dose 15 to 20 min. of the wine, with from 40 to 60 gr. of citrate of potassium, which should be administered three times a day. The citrate of potassium is given for its combined properties of acting as a diuretic and of diminishing the acidity of the urine, and may, if desired, be used as an effervescing mixture, 30 gr. of potassium bicarbonate to 20 gr. of citric acid. Colchicum reduces the gouty inflammation, relieves pain, and shortens the attack. It should only be taken under medical advice, and never in such doses as to produce extreme depression; after the inflammation of an acute attack has subsided, the colchicum should be gradually diminished until it is discontinued.

A very useful method of administering colchicum is in the form of its active principle, colchicine, which may be given in doses of $\frac{1}{80}$ to $\frac{1}{50}$ gr., three or four times a day immediately after food. Only a few patients will tolerate the larger doses, the contra-indications being the production of diarrhoea and intestinal griping. The following constitutes a very useful pill :—

R Colchicinæ	gr $\frac{1}{80}$	Extracti Hyoscyami	gr $\frac{1}{2}$
Sacchari Lactis	gr $\frac{1}{4}$	Extracti Gentianæ	gr j
Extracti Nucis Vomicae	gr $\frac{1}{4}$		

Three or four grains of blue pill should be given the first night of an acute attack, followed by a dose of Epsom salts in the morning. Mercury should be given only in sufficient doses to produce its cholagogue effect, as, owing to the possibly defective action of the kidneys, the mercury absorbed into the general system may be eliminated with difficulty. In the employment of purgatives for gouty patients, the great object is not to produce powerful purgation, but to relieve portal congestion and intestinal catarrh. A pill containing either euonymin 2 gr. or podophyllin $\frac{1}{4}$ gr., combined with extract of hyoscyamus $\frac{1}{4}$ gr. and compound extract of colocynth $1\frac{1}{2}$ gr., will, in many cases, be found very useful.

If the pain of an acute attack of gout is so severe as to prevent sleep, veronal or trional may be given, or a full dose of extract of hyoscyamus with blue pill at night will, in some cases, act as a very useful anodyne. The administration of opium or morphine should, if possible, be avoided, owing to the risk of its deficient elimination, and also on account of its diminishing the amount of urine, and its tendency to derange digestion and check hepatic metabolism.

2. Subacute and Chronic Gout. *Means of checking the Excessive Formation of the Toxic Agents of Gout.*—These consist in careful attention to diet and regimen, the promotion of the metabolism of the liver, and the relief of congestion of the portal system, which can be effected by keeping the bowels open at least once a day. In addition to colchicum in small doses, guaiacum may usefully be administered, as an alterative which stimulates the metabolism of the liver and also affords relief to the portal system. From 5 to 10 grains of guaiacum resin should be given in cachets two or three times a day, according to the effect on the bowels, since guaiacum sometimes acts as a laxative. The powdered guaiacum resin given in cachets is far preferable to the tincture of guaiacum in a mixture, as in the latter form a nauseous medicine is produced, and the precipitated resin may cling obstinately to the tongue and fauces. In cases of chronic gout the colchicum may very conveniently be administered in the form of the colchicine pill, three times a day. Colchicine, however, should not be given in marked interstitial nephritis, as in such cases a fatal result has been known to follow its administration in medicinal doses. Should constipation occur, a sulphur-and-guaiacum tablet 3 gr. each, or compound liquorice powder, may be administered at night. An occasional dose of blue pill and euonymin, followed by a purge of Epsom salts, will be found useful. If the patient is suffering from atony and debility of the stomach, nux vomica or strychnine may be given with potassium citrate. Iron preparations are not as a rule well tolerated by the gouty; but if anæmia is present, the citrate of iron and ammonium, or the carbonate of iron, will be the best to administer.

Means of promoting the Elimination of the Toxic Agents of Gout.—This may be effected by medicinal treatment, and by diet and regimen. Citrate or bicarbonate of potassium should be employed as a diuretic which increases the volume of the urine while it diminishes its acidity. The use of the potassium salt may with advantage be pushed until moderate alkalinity of the urine is produced; by such means the quadri-urates are rendered more soluble and stable

than they are in acid urine, and the tendency to the deposition of uric acid or sodium biurate in the kidney tissues is removed. Free diuresis should also be encouraged by the drinking of sufficient quantities of water. A gouty patient should avoid the excessive use of common salt at table, owing to its power in diminishing the solubility of sodium biurate, and thereby hastening the precipitation of that body.

The use of Alkalies and the Salts of Alkalies.—Of the potassium salts the citrate and the bicarbonate are the two most commonly employed. I am fully assured as to the beneficial effects of employing a potassium salt in conjunction with colchicum in the treatment of acute and subacute gout, and in my experience the citrate is the most useful. If given in sufficiently large doses it tends, by its conversion into the carbonate within the kidneys, to diminish the acidity of the urine (which is generally high in connection with the gouty paroxysm), while at the same time it increases the solvent power of the urine for the uric acid salts, and so assists their elimination. In cases of sluggish action of the liver, of gastro-intestinal catarrh and torpor, of gouty dyspepsia, and of other forms of irregular gout where there are no appreciable uratic deposits in the joints, mineral waters containing sodium salts are undoubtedly beneficial, owing to the action of those salts as hepatic and gastro-intestinal stimulants.

The lithium salts, in my opinion, are not so useful as the potassium and sodium salts. The chief objection to their use is their greater toxicity and depressing action on the heart as compared with the potassium salts. They consequently have to be given in such small doses that I am doubtful whether they possess any remedial effect. On the other hand, I constantly meet with patients suffering from cardiac depression as the result of the excessive and continued consumption of lithia tablets, which are so persistently, speciously, and wrongly vaunted as curative of gout.

In gouty conditions associated with disturbance of the functions of the liver, the most important consideration is the restoration of that organ to its normal activity, and here the alkaline sodium salts are especially useful. There is no better treatment at the outset than a dose of blue pill or calomel at night, followed by Epsom or Carlsbad salts in the morning. Subsequently, a pill containing a small dose of blue pill or calomel combined with euonymin and colocynth will be found most useful. In such cases a mixture which I have found most beneficial in stimulating the liver, and also the gastro-intestinal tract, is one containing sodium bicarbonate, gentian, and nux vomica, taken a quarter of an hour before meals.

Atophan is a drug which is decidedly useful in some cases of subacute and chronic gout. It should be given in doses of 15 gr. four times a day, and preferably administered in cachet form.

Further Treatment of Chronic Gout.—The enlargement and tenderness of the gouty joints is due to two causes—the deposition of sodium biurate in the cartilages and fibrous structures, and a chronic inflammatory thickening of the fibrous tissues. For the reduction of this last-mentioned thickening, as well as for painful gout of the sole of the foot, and for gouty neuralgic affections, iodide of potassium given internally is a useful remedy. This drug should not, however, be regarded as a solvent of gouty deposits, and it is contra-indicated if advanced kidney disease exists. It should be given in doses of 5 to 10 gr. three times a day, and may usefully be combined with from 5 to 10 min. of weak tinct. iodine (B.P.).

3. The Local Treatment of Gouty Joints—If there is much persistent swelling, the limb should be elevated as much as possible, and a light flannel bandage applied to the joint. If the œdema continues, the hot douche, followed by sponging with a cold strong solution of common salt, will be found serviceable. The application of the so-called solvents of uric acid externally is useless, as they

are not solvents of sodium biurate. Careful massage and gentle exercise of the stiffened joints should be employed, but only when convalescence is fairly established. The Scotch douche is very useful when the conditions are chronic. A good-sized stream is thrown with considerable force upon the affected joint, employing first cold water for half a minute, and then hot; the latter should be as hot as the patient can bear, and should be continued for one minute. This process is repeated for fifteen or twenty minutes. The repeated alternations of temperature produce a stimulating effect upon the circulation about the joint, and so increase tissue change and favour absorption. Massage of the joint should be resorted to immediately after the douching, as the tissues are then in a relaxed condition.

In many cases of chronic articular gout, the salt pack is efficacious. It consists of flannel soaked in a warm saturated solution of common salt, which is wrapped round the part, covered with oiled silk and a bandage, and kept on all night. It should be repeated nightly as necessary. For the stiffness and thickening of joints, careful rubbing with iodide of potassium and soap liniment may also be employed. The thermal baths of Bath, Buxton, Harrogate, Strathpeffer, Llandrindod Wells, Aix-les-Bains, and other spas, and mud baths, are useful in the treatment of these cases. Treatment by baths should, however, be avoided by patients suffering from acute gout, by very old people, and by those suffering from any serious cardiac affection.

Massage, Electricity, and Baths.—A sedentary life and deficient exercise conduce to gout, owing to a lowering of general metabolism, to depressed vigour of blood-circulation, and to impairment of movement in the lymph-channels. Since the lymph-circulation is mainly carried on by muscular movements and respiration, the beneficial influence of massage and muscular movements on many gouty subjects becomes readily intelligible. Massage should never be resorted to in cases of acute gout, as it not only aggravates the disease at that stage, but also causes severe pain; it should be reserved for the more chronic cases. Massage produces an increase in the amount of blood and lymph passing through the tissues concerned, at the time and afterwards. This improves the nutrition of the affected tissues, promotes absorption of deposits, and restores physiological activity. In subacute or chronic cases, where the joints remain swollen and œdematous and are the seat of considerable deposits, much benefit is frequently derived from massage and galvanism. Each of the affected joints should be massaged for a few minutes, and then galvanism (5 to 10 milliampères) applied for a few minutes with the negative pole over the affected region, to be again followed by massage. Under this combined treatment the œdema and deposits frequently disappear rapidly. Probably the beneficial effects are due mainly to the increased circulation of blood and lymph induced, and the consequent absorption that takes place. I have also found, in many cases, that a decidedly beneficial influence on gouty joints is produced by electric-light baths, followed by electrical treatment in the form of cataphoresis to the affected joints.

Electric-light and superheated-air baths increase the oxidative processes within the body, as is shown by the increased elimination of carbon dioxide from the lungs, and also by the increased metabolism of the body in general. They also stimulate the circulation of the blood and lymph in the affected joints, and so lead to improved nutrition. This curative action undoubtedly continues after the treatment has been discontinued. Such treatment, therefore, is better given intermittently, say six baths on alternate days; then intermit for two or three weeks, and so on. These baths improve the atrophic condition of the muscles. They cause a temporary elevation of the body-temperature, marked reddening of the skin of the part treated, profuse local or even general perspiration, quickened pulse, lowered arterial tension, and generally considerable

amelioration of the pain, and in some cases complete disappearance of it for a time. Radiant heat has a greater penetrative effect than other forms of heat, and in my opinion the effect is more stimulant. In cases of acute or subacute gout, the pain, as a rule, recurs at varying intervals after a bath, but usually with diminished severity; and frequently a progressive reduction of the pain occurs after the use of subsequent baths. Undoubtedly many cases of chronic gout do not show much improvement after the use of electric-light or superheated-air baths, and I have frequently experienced great difficulty in selecting the patients most likely to be benefited by them. In my experience, chronic gout of long standing, with considerable deposits in the joints, is not much benefited by these baths; for such cases undoubtedly more good can be done by the employment of vapour baths, followed by massage of the affected joints, a method which is frequently most useful in producing softening and absorption of the deposits. Electric-light baths, however, seem to set up improved circulatory and trophic changes in the joints, which are maintained long after the baths have been discontinued. If only one limb is attacked, the question arises as to whether that limb should be locally treated by being placed in a small specially-constructed bath, or whether the "entire body" bath should be used. In my experience, the last is always the more useful, with, in the case of the electric-light bath, an extra localization of the heat and light rays on the affected part. That means that the more extensive the surface to which the heat and light rays are applied, the better is the result. When these baths are not obtainable, very good results may be obtained by the use of an ordinary blanket-tent with a small opening at the top to let out the hot air saturated with moisture. The hot air is supplied by a ring Bunsen gas-burner, or by a large spirit-lamp with a flue passing through an opening in the blanket at the foot of the tent.

Cataphoresis is useful in many cases of chronic gout with considerable deposits in the joints. By cataphoresis is meant electric osmosis, or the transfer through porous partitions from anode to cathode. The joint may be treated either by immersion in a local bath of the fluid which is to be introduced, the positive electrode being placed in the bath and the negative on the back, or the positive electrode may be kept thoroughly wet by frequent applications of the fluid. The negative electrode should be a large one, about 8 inches by 5 inches, made of zinc, and protected by a flannel cover. It is well moistened with warm water and applied to the lumbar or dorsal region. At the positive pole either potassium bicarbonate or lithium iodide may be introduced into the affected joint. In the former instance the positive electrode is kept thoroughly wet with a saturated solution of potassium bicarbonate; in the latter, the joint is painted over with iodine liniment, and a pad of lint soaked in a saturated solution of lithium carbonate is laid over the iodine surface; on the lint the positive electrode, which should be a large flat one, is placed, and closely applied to it. Care must be taken to have everything *in situ* before turning on the current, so as to avoid any shock, and to give an easy, steady flow of current.

Currents of from 10 to 30 milliamperes may be employed. For the treatment of gouty neuritis, constant-current baths are usually most beneficial; electric-light or superheated-air baths, followed by the use of the constant current, generally do an equal amount of good. In the acute or subacute stage of gout, or when a slight attack has just started, the Turkish bath is most undesirable. I have known of its employment in such cases being followed by an exacerbation of the attack, and extension to joints not at the time affected. This is a point which should be borne in mind by medical men, as many patients on the first appearance of an attack are apt to have immediate recourse to the Turkish bath, and it is well that they should be warned of the danger they thereby incur.

Treatment of Irregular Forms of Gout.—*Gouty Eczema.*—In this condition,

special attention should be given to two details: (1) See that the bowels are freely opened, which at the outset may be secured by the administration of blue pill or calomel, followed by a saline; (2) Entire abstinence from alcohol is most desirable, at all events during the persistence of the eczema. It is best that any form of alcohol should be abstained from, but more especially, in my experience, the red wines. I have met with cases occurring among gouty individuals past middle age in whom two or three glasses of claret or burgundy will, in the course of a few hours, cause the development of an eczema. During the irritative stage of dry gouty eczema, I have found the application of a lotion consisting of liquor plumbi subacetatis 1 dr., liquor carbonis detergens 1 dr., aqua sambuci ad 1 pint, most soothing, especially if followed by the use of a simple dusting-powder, such as cimolite powder. For the acute moist type of eczema a similar lotion, but with a preparation of opium replacing the tar solution, is advisable. In cases of gouty pruritus, or, as it is sometimes termed, latent gouty eczema, the severe itching is frequently relieved by the use of carbolie acid lotion. When the eczema is in a chronic condition, much benefit is usually experienced from immersion in sulphur baths, such as those of Harrogate, Strathpeffer, Aix-les-Bains, etc. After the bath the skin should be carefully dried, and a dusting powder, such as cimolite powder, freely applied. In cases of gouty eczema and gouty pruritus, a careful dietary must be enforced, care being taken to forbid all articles which the experience of the patient has shown to produce dyspepsia. Such persons should avoid acid fruits, as strawberries, gooseberries, apples, and pineapples; rhubarb also should be excluded from the dietary. As regards the medicinal treatment, my experience is that it is not necessary to give the ordinary anti-gout remedies, such as colchicum, etc. It is much more important to treat the dyspepsia and the catarrhal condition of the gastro-intestinal tract which are generally present as associated or causative conditions, by the administration of subcarbonate of bismuth with the bicarbonate of sodium or the bicarbonate of potassium.

Hyperchlorhydria.—The treatment of this condition consists in a proper regulation of the diet, by cutting off any excess of the protein articles of diet and by neutralizing the superfluous acid by the administration of some alkali. A drug that I have found most useful in the treatment of this hyperchlorhydria is hopogan (magnesium peroxide). It not only gives immediate relief to the pain and discomfort by its neutralizing effect on the excess of acid, but it also parts with one half of its oxygen and acts as an internal antiseptic. It is a most valuable drug in many abnormal gastric and intestinal fermentations. It is a white tasteless powder, and is best given in a little milk, in doses of 20 to 30 gr. three or four times a day, taken one hour after meals. If it exerts too great a purgative effect the dose should be diminished. It is also very useful in allaying the irritation in many cases of gouty pruritus, which is probably due to absorption of a toxin or toxins from the intestinal tract.

Hepatic Torpor.—A very common form of irregular gout is due to defective metabolism of the liver, and is known as hepatic torpor, or hepatic inadequacy. In this form, the fæces are pale, generally very offensive, and, as a rule, constipation occurs. Slight jaundice is usually present, as evidenced by a yellowish conjunctiva and muddy complexion, and the urine is highly coloured, of high specific gravity, and very acid. In the treatment of this form of irregular gout the most important consideration is the restoration of the liver to its normal state of activity, and here the alkaline sodium salts are especially useful. There is no better treatment at the outset than a dose of "blue pill" or calomel at night, followed by a dose of Epsom salts or Carlsbad salts in the morning. Subsequently, a pill containing a small dose of "blue pill" or calomel, combined with euonymin and colocynth, will be found most useful. In such cases of gouty

hepatic inadequacy, a mixture which I have found most beneficial as regards its stimulating effect on the metabolism of the liver, and also of the gastro-intestinal tract, is the following, which should be taken a quarter of an hour before meals :

R Sodii Bicarbonatis	gr xij	Spiritus Chloroformi	℥ xij
Tincturæ Nucis Vomiceæ	℥ xv	Aquam Menthæ Piperitæ	ad ʒj
Tincturæ Gentianæ Co.	ʒ ss		

Gouty Phlebitis.—For the treatment of this fairly common form of irregular gout the patient should be kept in the recumbent position, and any sudden movement of the affected limb must be prevented on account of the danger of detaching a portion of thrombus and the occurrence of consequent embolism of the pulmonary artery. Equal parts of glycerin and extract of belladonna should be smeared over the affected part, and a linseed poultice, with some of the glycerin and extract of belladonna spread on the surface, should be applied and renewed every six hours. In addition to this, the ordinary treatment of the gouty state must be resorted to.

Gouty Dyspepsia.—In addition to the usual remedies, such as bismuth subcarbonate, sodium bicarbonate, bitters, etc., taka-diasase is a most useful drug in this affection. It is made up in the form of tablets containing $2\frac{1}{2}$ gr., and one of these should be taken immediately before each meal. The taka-diasase encourages the digestion of the carbohydrates, and so prevents the development of fatty acids, which, by their irritating effects, are so common a factor in the development of gouty dyspepsia.

Insomnia.—This is a fairly common symptom in gouty patients. Usually it is not complete, but confined to restlessness, interspersed with intervals of light or broken slumber. In such cases attention should be paid to the patient's pulse, and to the possible existence of albumin in the urine. If, as is frequently the case, the pulse is found to be of high tension, the administration of blue pill or calomel, followed by a saline purge, will probably prove most beneficial.

With regard to the use of tobacco, the majority of gouty patients may be permitted a moderate indulgence in smoking, but it should be avoided entirely by those who suffer from paroxysmal attacks of the gouty heart.

PREVENTIVE TREATMENT.—I have now had a considerable experience of the prophylactic effects of guaiacum resin, and I know of no drug which is more useful in the preventive treatment of gout. Its action is probably due to its stimulating effect on hepatic metabolism, thereby increasing, as it undoubtedly does, the elimination of uric acid. I prefer to give it, as explained above, in the form of the powdered resin in cachets, commencing with doses of 5 gr. three times a day after meals, and gradually increasing the dose to one of 10 to 12 gr.

Mineral Waters.—The value of a given mineral water in the treatment of gout depends greatly on the object with which it is taken. For instance, it may be given to remove gouty deposits, to stimulate the action of a sluggish liver and to relieve portal congestion, for the treatment of gouty dyspepsia, to relieve the bowels in cases of torpor and gastro-intestinal catarrh, to act on the kidneys, or to relieve gouty affections of the skin. It is manifest that any one mineral water is not likely to produce all these effects, and it is also conceivable that a water which might effect one of these purposes might prove injurious if employed to fulfil another. No doubt considerable error has arisen from indiscriminately sending gouty patients to a particular spa, without duly considering whether the water of that spa is suited to the specific gouty disorder from which the patient is suffering.

There is a tendency with some medical men to consider that the efficacy of a natural mineral water is due solely to its watery constituent; in other words,

that its one therapeutic use is that of a flushing agent. On the other hand, an exaggerated importance is not infrequently attached to the particular salts contained in a mineral water as ascertained by chemical analysis. The fact is, that in judging of natural mineral waters we have been too much under the domination of analytical chemistry, and our deductions from these results have been consequently biased and cramped. The more I consider their therapeutic effects, the more convinced I am that chemical analysis, although it can inform us what their mineral constituents are, is yet unable to determine exactly the state of the salts dissolved in them. The "ionic or electrical dissociation theory," and the existence of the mineral constituents of natural waters as "ions," are leading our thoughts to a new and, I believe, more correct appreciation of the therapeutic values of these waters. In intimate relation with this aspect of the matter is the question of radio-activity as possessed by these waters. Most, if not all, which have been subjected to examination, have been found to be distinctly radio-active, and the lower the mineralization of the water, the more intense is its radio-activity. In this, I think, lies the explanation of the fact that an artificially prepared mineral water, although identical in chemical composition with the natural one, does not possess the same therapeutic effects, since it is lacking in the property of radio-activity. A natural water at the moment of its discharge from the earth is radio-active, whereas an ordinary drinking water does not possess this property to any appreciable extent. Hence also the desirability of drinking the water at its source, since by bottling and keeping a natural water the radio-activity is to a great extent lost.

Useful as may be the drinking of the water at a spa, yet equally, or even more, so is the encouragement of the functions of the skin by balneological methods for therapeutic purposes. The skin is the largest organ of the body, and it possesses various and complex functions. Amongst these are : (1) The excretion of toxic bodies, the retention of which prove harmful, and ultimately fatal, to the organism ; (2) The power it possesses through its nerve endings of stimulating distant organs and tissues, and (3) Its heat-regulating power. The success of balneology, whether in the treatment of chronic joint conditions, of affections of the fibrous tissue, of certain heart and kidney affections, or of certain skin diseases, depends upon the recognition of the powerful aid which can be given by the skin in restoring the normal balance.

If the view as to the intestinal origin of the toxæmia present in gout is correct, the value of mineral waters, both as curative and preventive agents, becomes at once intelligible, from the marked influence they have on the metabolism of the intestinal tract, and their power of removing by the bowels the antecedents of the toxin causing gout.

It is especially in cases of chronic gout, of gastro-intestinal catarrh and torpor, of gouty dyspepsia, sluggish action of the liver, gouty eczema, gouty glycosuria, and of other forms of irregular gout, that mineral waters prove so valuable ; whilst the various baths, combined with massage, are so useful in producing softening and absorption of the deposits in the joints and other tissues. Patients actually suffering from acute or subacute articular gout, or who are apparently on the verge of such an attack, are better without sulphur waters, as in such cases the waters tend to accentuate or precipitate an attack in the joints.

Choice of a Spa.—In the selection of a spa, so many factors have to be considered that it is impossible, in a work of this nature, to deal fully with the subject. I wish, however, to state clearly that the high state of efficiency to which our home spas have been raised, render it no longer essential to banish our patients to foreign health resorts, and that, unless a complete change of environment is desired by our patients or is essential to their recovery, treatment can, in the great majority of cases, be carried out as effectually in our own country.

The following table may be of some value, as being an attempt to classify the therapeutic indications of mineral waters in the treatment of gouty conditions.

CLASSIFICATION OF THE VARIOUS MINERAL WATERS ACCORDING TO THEIR THERAPEUTIC VALUE IN THE TREATMENT OF THE VARIOUS FORMS OF GOUT.

OBJECT OF TAKING THE WATER.	THE WATERS BEST SUITED TO THE PURPOSE.
Absorption of gouty deposits from the joints and tissues.	Bath, Buxton, Contrexéville. Gastein, Harrogate, Pfäfers, Strathpeffer, Teplitz, Vittel, Wildbad, Aix-les-Bains (for baths).
Treatment of gouty dyspepsia.	Brides-les-Bains, Carlsbad, Ems, Harrogate, Homburg, Kissingen, Neuenahr, Royat, Vals, Vichy, Wiesbaden.
Treatment of gouty congestion and torpor of the liver, and of gastro-intestinal catarrh and torpor.	Baden-Baden, Bourbonne, Carlsbad, Cheltenham, Contrexéville, Harrogate, Homburg, Kissingen, Leamington, Llandrindod, Marienbad, Neuenahr, Tarasp-Schuls, Vals, Vichy, Vittel, Wiesbaden.
Treatment of gouty affections of the respiratory organs.	Ems, Royat.
Treatment of gouty glycosuria and diabetes.	Carlsbad, Contrexéville, Harrogate, Kissingen, Leamington, Llandrindod, Marienbad, Neuenahr, Strathpeffer, Vals, Vichy, Vittel.
Treatment of gouty skin affections.	Aix-les-Bains, Baden, Bagnères-de-Luchon, Harrogate, Llandrindod, Schinznach, Strathpeffer.

DIET IN GOUT.

No hard and fast lines as to dietary can be laid down. Each individual must be carefully considered as regards his habit of body, his capacity for the digestion of different articles of food, the amount of exercise he is able to take, and the nature of his work. Derangements of the gastro-intestinal tract constitute a most important factor in the development of acute, chronic, and irregular gout. It is of the utmost importance to secure and maintain a healthy condition of the gastro-intestinal mucous membrane and a normal daily evacuation, in order to guard against auto-intoxication, which is undoubtedly an early factor in the development of the gouty condition. The patient can certainly diminish the number and severity of the attacks, and in many cases prevent their recurrence, by careful attention to diet, to the quality and the quantity of fluid taken, to exercise, and to a sufficient daily action of the bowels. In advising as to diet, the personal factor is a most important one, and it is wise to gain some knowledge as to the likes and dislikes of the patient with regard to food. In this connection it is well to remember the saying of Sydenham, that "more importance is to be attached to the desires and feelings of the patient, provided they are not excessive, than to doubtful and fallacious rules of medical art."

It should be well borne in mind that great changes in diet should not be made too abruptly. The researches of Pawlow show that a habit of digesting easily

any particular kind of food is acquired by the stomach, which secretes a gastric juice appropriate to it, so that if the food is suddenly changed, time is required for the digestive organs to accommodate themselves to the altered conditions. If the change is too sweeping and too abrupt, the patient will probably suffer. It is well known that the excessive consumption of rich nitrogenous food combined with excesses in wine and malt liquors both induce and excite gout. The comparative immunity of females and young people is mainly explained by the absence of such determining causes, combined with (in the case of young people) the absence of predisposing cause, and also the fact that the secreting functions are in full activity. The subjects of gout are generally persons who live well and consume a large amount of animal food.

Gouty people may, for dietetic purposes, be roughly grouped into three classes : (1) Those who suffer from more or less frequent attacks of acute gout ; (2) Those who have never suffered from an acute attack, but who are constantly subject to some chronic form of regular or irregular gout, especially after slight indiscretions in diet ; (3) Those who are only affected with gouty symptoms (generally of the irregular kind) when they eat or drink certain articles, and who therefore have to be specially watchful over their diet.

Animal Food.—It must be remembered, on the one hand, that animal foods constitute to the majority of people the most attractive and appetizing forms of diet, and are therefore likely to be taken in excess ; hence the necessity for limiting the amount to be taken. On the other hand, it is most desirable to increase the combustion and the oxidative powers within the tissues. In my opinion, it is absolutely erroneous to exclude from the dietary of the gouty such articles as meat, fish, and tea because they are assumed to contain uric acid. No class of food-stuff gives so great an amount of energy and produces so much heat as animal food,* and no class is more easily digested by the majority of gouty people. On the whole it may be stated that animal food such as fish, chicken, game, and meat, is best suited to the majority of cases, whilst foods of the farinaceous class are most likely to disagree. White meats, such as chicken and fish, are more digestible than red meats. The quantity of meat, and especially of red meat, must be restricted in those cases in which the kidneys are imperfectly performing their eliminatory functions, as evidenced by a pale urine, of low specific gravity, deficient in urea and purin bases.

Vegetable Food.—A fair proportion should be taken with two meals each day. The choice of vegetables will depend upon the digestive capacity of the patient, but, excepting the potato, as a rule those that grow above ground are preferable to root vegetables. At the same time it must be borne in mind that with certain patients some of these vegetables may produce some form of dyspepsia, and I cannot too strongly urge that in the dieting of the gouty no hard and fast rules can be laid down, but the idiosyncrasy of each patient to various articles of food must be made the subject of careful observation and study. Due consideration should also be given to the patient's experience of what articles of diet disagree and agree with him.

Simplicity of Meals.—The diet should be simple, that is, the meals should not be made up of too many articles. Simplicity of food means facility of digestion. Moderation in both eating and drinking is perhaps one of the most essential points to insist on. Certainly meat, even red meat, should not be excluded. Those articles of diet that are known in the individual to favour intestinal fermentation and putrefaction should certainly be avoided, and, speaking generally, a sense of discomfort after a meal indicates that some food has been taken which is not beneficial to the individual in his present condition. If the gouty symptoms are due to over-production of toxic material from faulty intestinal and hepatic metabolism, and if, at the same time, the kidneys are

* Fats contain twice as much potential energy as proteins.—AMERICAN EDITOR.

sound, then a diet which mainly consists of animal food is indicated; and in extreme cases of this class, even the so-called "Salisbury diet" may be useful. If, on the other hand, the symptoms are due to defective elimination on account of diseased kidneys, then a more vegetarian diet will be best. The value of the so-called "Salisbury diet" consists in the small amount of energy necessary for the digestion of so simple a diet, and in the fact that it contains little which can set up intestinal fermentation or putrefaction. On the other hand, a strictly vegetarian diet requires more digestive energy than a purely animal one, and a much larger quantity of vegetable food must be taken to produce an equal nutritive effect. If, during the treatment of gout, an attack of gouty dyspepsia should intervene, a milk diet should be employed until the dyspeptic symptoms have abated.

Starchy and Saccharine Foods.—Starchy foods should be especially limited in amount in those individuals who are subject to gastric hyperacidity (hyperchlorhydria). When intestinal fermentation and putrefaction occur, as evidenced by a sense of discomfort after a meal, I attach great importance to the reduction of the starchy articles of food, but not to the total exclusion of—what I believe to be comparatively harmless—the potato. Undoubtedly, amongst patients who suffer from an inability to digest starchy articles of diet—in other words, from amylaceous dyspepsia—a reduction for the time in the amount of starchy foods taken, including potatoes, is desirable; but the recognition of the existence of amylaceous dyspepsia is a fairly easy matter, and, when present, it can be suitably treated. Certainly those who are gouty and fat should be very sparing in the use of potatoes, as of other carbohydrates. I wish, however, to protest against the too general exclusion of so common and useful an article of diet as the potato.

Potatoes can best be taken by the gouty in the crisp form, which requires thorough mastication and insalivation. Boiled new potatoes should be absolutely interdicted.

Equally wrong, in my opinion, is the total exclusion of sugar from the dietary of all gouty individuals. Undoubtedly in certain cases sugar may do harm, as in persons who are fat, who suffer from glycosuria, or who are prone to attacks of eczema,—in such it should be cut off; but that is no reason for the exclusion of it from the dietary of all, and especially those who are, at the same time, gouty and thin; such subjects may also take in moderation marmalade and wholesome jams. I know of many gouty individuals who take sugar with absolute impunity. Some subjects undoubtedly digest all starchy articles of diet very badly, and, in such, fats may well take the place of starches. Fat bacon, properly cooked, is generally well digested. Bread may advantageously be given as crisp toast, in the form of rusks, or in the "zweiback" or twice-baked form, as in these conditions it requires thorough mastication and insalivation.

Fruits.—Any fruit, which from experience is known to agree with the patient, may be taken. Apples and oranges generally do best. Uncooked fruit should never be taken at a meat meal, and is best consumed fasting, fairly early in the day, as between breakfast and lunch. It should always be thoroughly masticated. Strawberries are frequently avoided owing to their producing in some subjects a certain amount of temporary irritation of the skin, but this generally passes off in a short time. In a few subjects, strawberries produce eczema or some other rash; but such cases merely represent idiosyncrasy to the special fruit, and necessarily such individuals, whether gouty or not, should not eat strawberries. I am, however, strongly of opinion that the indiscriminate banishment of strawberries from the dietary is unnecessary. Except in these cases, they constitute a good article of diet for the gouty, on account of their delicious flavour, their antiscorbutic properties, and their richness in potassium

salts. It is very necessary that they should be ripe and fresh. They quickly decompose, and in such a state aid in the development of those intestinal fermentations which are so inimical to the gouty.

Alcoholic Drinks.—Stated as a general principle, a person who is subject to gout is better without alcohol in any form. There are, however, some who require a little alcohol, either to aid digestion or to enable them to get through their work. If alcohol is necessary or desirable, the form in which it is to be taken is frequently a matter which the patient can decide better than the medical man; but I would insist upon the importance of definitely limiting the amount to be taken, and of restricting its consumption absolutely to meals. Some patients find a little whisky or brandy suits them best, others prefer a light still Moselle, while a very few find that a light claret agrees best with them. Champagne is seldom suited to the gouty, especially if taken daily. In elderly or feeble people, a moderate amount of pure whisky undoubtedly does good, but the indiscriminate ordering of whisky is, I am sure, wrong. Port is especially unsuited to the majority of gouty subjects, its gout-producing properties, I believe, being mainly dependent upon the ethereal compounds which give the aroma or bouquet to the wine. If this view is correct, it would explain the well-known fact that old and matured ports are much more provocative of gout than comparatively new ports taken direct from the wood. The development of the ethereal compounds in the wine extends over many years, and especially progresses after the wine is laid by in bottles. In a few cases of asthenic gout, especially in old people, a moderate amount of comparatively new port, taken direct from the wood, undoubtedly does good.

In my opinion the wines which are least injurious as a rule to gouty subjects to whom it is found necessary to order a small amount of wine, are the light, still, white wines, such as Moselle, certain French and Austrian wines, hock, and a few of the lighter Australian and Californian wines. The latter, owing to their greater alcoholic strength, should be taken diluted with water or some mineral water.

Patients suffering from glycosuria or diabetes should entirely abstain from alcoholic drinks, unless marked debility and loss of appetite necessitate the restricted administration of them. Those subject to attacks of eczema are also much better without alcohol in any form.

"Rough cider," that is, the completely fermented apple-juice, taken in moderation, agrees well with most gouty subjects. It contains but a small percentage of alcohol, is free from sugar, and its acidity is chiefly due to malic acid, which passes into the circulation in the form of alkaline malates, which in their turn are converted in the kidneys into alkaline carbonates and excreted as such, thereby increasing the elimination of urates. The bottled or "champagne" cider, which is imperfectly fermented, should never be used, owing to its undoubted liability to set up gastro-intestinal fermentations. Dry or "rough" cider, mixed with an equal quantity of an aerated water, is an excellent beverage. Dry perry is also a suitable drink for the subjects of gout.

Diet in Acute Gout.—During the attack a diet must be given which shall tend to check the abnormal metabolism of the gastro-intestinal tract and of the liver, which shall be non-irritating to the kidneys, and one that diminishes the production of the purin bodies. For the first day or two the patient should be restricted to a milk diet, which may consist of milk, bread-and-milk, and tea made with boiling milk instead of with water. Weak tea, with cold toast thinly buttered, may also be taken. The free drinking of hot or cold water, Salutaris water, or of some mineral water free from sodium salts, should be encouraged. The milk diet should be continued until the acute inflammation

is subsiding, which stage is indicated by the lessening of the pain, and by the pitting, on pressure, of the affected parts. No alcohol in any form should be given during this stage, unless there are strong reasons for its administration, such as a weak action of the heart and a feeble, irregular pulse, when a little well-matured whisky or brandy, diluted with *Salutaris* water, will prove the best form of alcohol. Beef-tea and any of the meat extracts or essences should be avoided at all times by gouty patients, owing to their tendency to irritate the kidneys, and to introduce into the circulation waste nitrogenous bodies. With the subsidence of the acute attack the patient may return to a more liberal diet, care being taken to avoid anything indigestible.

ARTICLES OF DIET THAT SHOULD BE AVOIDED BY THE GOUTY.

Rich meat soups: oxtail, turtle, mock turtle, kidney, mulligatawny, hare, giblet.

Salmon, mackerel, eels, lobster, crab, mussel, salted fish, smoked fish, preserved fish, tinned fish.

Duck, goose, pigeon, high game.

Meats cooked a second time, hare, venison, pork, lean ham, sweetbread, liver, kidney, salted, corned, or cured meats, pickled meats, preserved and potted meats, sausages; all articles of food pickled in vinegar; all highly seasoned dishes and rich sauces.

Tomatoes, beetroot, cucumber, rhubarb, mushrooms, truffles.

Rich pastry, rich sweets, new bread, cakes, nuts, dried fruits, ices, ice cream.

DIET SUITABLE IN CHRONIC GOUT AND FOR GOUTY SUBJECTS.

Morning.—Half a pint to a pint of hot water, flavoured with a slice of lemon peel, should be slowly sipped immediately on rising.

Breakfast.—A selection may be made from the following articles of diet, according to the taste of the patient: Porridge and milk, whiting, sole, or plaice, fat bacon, eggs cooked in various ways, dry toast or “zweiback bread” thinly buttered, and tea infused for three minutes and then strained from the leaves. Fat bacon is digestible when grilled, but less so when boiled. Eggs should not be taken hard-boiled.

Lunch and Dinner.—Soups suitable for the gouty are vegetable purées, and soups made by boiling beef bones or mutton bones with vegetables, and subsequently removing the fat, which separates on cooling. These soups should not be thickened with farinaceous substances.

The varieties of fish most suitable to the gouty are whiting, sole, turbot, plaice, smelt, flounder, grey mullet, and fresh haddock.

The birds that are admissible as articles of diet are chicken, pheasant, turkey, and game (not high).

Butcher's meat—mutton, lamb, and beef—should be taken at only one meal in the day, and then in moderate quantity. Two vegetables may be taken at both lunch and dinner. Any of the ordinary vegetables may be taken, except those previously mentioned as best avoided; but those that are most likely to prove beneficial to gouty subjects are spinach, Brussels sprouts, French beans, winter cabbage, Savoy cabbage, turnip-tops, turnips, and celery. Potatoes may also be taken in moderate quantities. Stewed fruits, or baked apples or pears, may be taken every day at one meal.

Green vegetables as salads may be taken, provided oily dressings are avoided. A simple savoury may, if desired, be taken at the end of dinner, or a small quantity of cheese, if well masticated, and if free from the fungus or mould.

Night.—Half a pint to a pint of hot water, flavoured with a slice of lemon-peel, should be slowly sipped before retiring to bed.

* * * *

With regard to persons who are disposed to gout, but are not actually suffering from it, the usual mixed diet may be taken, but they should limit the starchy articles of food, and should avoid all rich sweets, rice, tapioca, and sago. Thin and ill-nourished subjects require modifications in their diet as compared with those who are stout; while those who take plenty of exercise may be allowed food forbidden to the indolent. Individuals who especially benefit by a reduction of diet, both as regards quantity and quality, are those overfed people who are past middle life.

GUMS.—(See JAWS, TUMOURS OF.)

GUNSHOT WOUNDS.—Speaking generally, the treatment of gunshot wounds differs but little from the treatment of wounds inflicted in other ways. While this statement is true of civil practice under normal conditions, it must be realized that gunshot wounds in warfare have in some respects to be treated on different lines. Such circumstances as the impossibility of efficient sterilization, the limiting of staff and equipment, the necessity of treating the wounded without shelter in an atmosphere of dust and dirt, and the prospect of long and trying transport in crowded wagons to a far-removed stationary hospital, must obviously modify the more ideal methods which should be adopted in every-day practice. It is necessary to emphasize this distinction, as the attempt to treat gunshot wounds in warfare on the lines here laid down will not infrequently result in disappointment and failure.

FIRST AID.—The wound is to be interfered with as little as possible. A pad of antiseptic gauze is placed over the apertures of entrance and exit without wiping or washing the wound in any way. The patient is removed immediately, with as little disturbance as possible, to a place where appliances and surroundings admit of efficient antiseptic treatment. *Hæmorrhage* is very rarely of any moment, but occasionally a large vessel in a limb is divided and calls for the application of a tourniquet as a temporary measure. Plugging the wound must be avoided.

GENERAL TREATMENT OF THE WOUND.—A pad of antiseptic gauze is placed over the bullet holes. The skin around is shaved, scrubbed with soap and water, and disinfected with antiseptic lotion (carbolic 1-40, or mercury perchloride 1-2000). The pad is then removed from the wound, and the aperture cleansed with the lotion, dried, and covered with a dry gauze dressing, and the part enveloped in wool. No attempt is to be made to wash out the track of the bullet with antiseptics. A simpler method of treatment is to paint the whole region, including the wound itself, with weak tinct. iodine (B.P.). If this course is pursued there must be no preliminary washing, and shaving, if necessary, must be done dry. A dry gauze dressing is then applied. This treatment is all that is necessary for a wound caused by a small-bore bullet which has completely traversed the soft parts; healing will usually take place without complications, a small

scab forming over the apertures. This type of "flesh wound" is that commonly met with in warfare, and the favourable result described is very frequently obtained. It must be remembered, however, that in civil life we more often have to deal with revolver bullet wounds; in the case of the most powerful weapons the bullet is large, and of lead without a hardened envelope; in the case of the smaller pocket revolvers the bullet is of small size, but the comparatively small charge means that the bullet frequently remains in the body. Moreover the weapon, except in those rare cases where a man is accidentally hit in the neighbourhood of a rifle range, is discharged at a distance of a few inches or feet, and in consequence not only is there more extensive laceration of the soft parts, but fragments of clothing or the wad of the cartridge may be carried into the wound. In these cases the same measures for disinfection of the skin are taken and the position of the bullet is ascertained by *x* rays. The track of the bullet, enlarged by a knife if necessary, is to be explored carefully with the finger. All foreign bodies are removed, and the bullet is located and extracted with bullet forceps or other suitable instrument. The wound is then freely irrigated, a small drainage tube inserted, and dry dressings applied. The drainage tube is removed at the end of forty-eight hours. It may be that the bullet cannot readily be reached from the original wound. If it be readily accessible from another position, it may be removed through a fresh incision at a convenient situation; but should it be deeply placed, and should it be obvious that an extensive dissection will be necessary for extraction, the bullet must be left alone. It will very likely give no trouble and the wound will heal well. Should it give rise to symptoms at a later date, the removal may be undertaken through healthy skin without fear of infection.

Wounds of Blood-vessels.—It is rare for a vessel of any magnitude to be injured, but if severe and persistent bleeding show this to be the case, the wound is enlarged freely and the vessel is ligatured. It should be remembered that the blood may collect in the tissues, forming a large hæmatoma, perhaps pulsating. The treatment is the same as for external bleeding.

Wounds of Nerves.—These should be treated on the lines laid down in the article on NERVES, INJURIES OF (*q.v.*). It must be borne in mind, however, that a condition known as "concussion of the nerve" is met with in gunshot wounds. The nerve is not obviously damaged—indeed it may be out of the track of the bullet—and yet all the symptoms of complete nerve division may be present. In doubtful cases, therefore, there should be delay before operating, since recovery without operation is often complete and rapid in cases of "concussion."

Wounds of Bones.—A small-bore bullet striking the cancellous end of a bone may perforate it, but with larger bullets (and even with small-bore bullets fired at short range) the bone, cancellous or compact, is often extensively comminuted, and there is a large ragged exit wound caused by the bullet driving before it fragments of bone. The wounds of entrance and exit are dealt with on the lines already laid down, and splints having been applied, the case is treated by the methods applicable to ordinary fractures. If, however, there be extensive comminution, with loose fragments torn from their periosteal attachments, with a large lacerated aperture of exit or with the bullet retained, the site of the fracture is to be explored. The wound (exit wound if it exist) is enlarged, all loose fragments removed, and the bullet extracted. The wound is well irrigated and drainage is provided for. If suppuration has occurred, the exploration described is always called for. Primary amputation is practically never needed.

Wounds of Joints.—A wound involving a joint is of serious import when it is accompanied by comminution of the articular ends of the bones. A favourable result, may, however, be anticipated when the bullet has left the bone uninjured

or has merely grooved or caused a clean perforation of its articular end. In this latter class of case the external wounds are dealt with as already described, the joint is kept at rest until the wounds are scabbed over (usually after a week), and then massage and movements are resorted to. In the former class, with severe comminution, the joint is laid open, the loose fragments are removed, and the joint is irrigated and drained; passive movements are begun early. If a bullet be lodged in a joint it must be removed. In any case where suppuration occurs, free drainage of the joint is called for, and frequent irrigation; if these measures fail, amputation may be necessary. Excision may be called for later—to restore movement in the shoulder or elbow, or to remedy ankylosis in a faulty position in the knee.

Wounds of the Skull.—These injuries are often immediately fatal. With the modern military rifle the bullet may completely traverse the skull, leaving apertures of entrance and exit. Revolver bullets often remain within the cranial cavity. Operation is necessary. Flaps are turned down exposing the points of entrance and exit. Both bony apertures are enlarged by forceps or trephine in order to allow of digital examination, and all splintered or depressed fragments are then removed. Should the bullet have ploughed a groove in the skull without penetrating the cavity, it is still necessary to trephine, since the inner table is extensively splintered. If the bullet has remained in the skull it is extracted if readily accessible, otherwise it is left; and should symptoms referable to its presence develop later, it may be localized by *x* rays and removed.

Wounds of the Chest.—These are treated on the usual principles. Morphia is administered if there be hæmoptysis, which is not as a rule severe. Hæmothorax, if of any amount, is dealt with by aspiration.

Wounds of the Abdomen.—In civil practice these wounds are treated as other penetrating abdominal wounds (see **WOUNDS OF THE ABDOMEN**). The abdomen is opened immediately and the damage to the viscera is repaired. Multiple visceral injuries are the rule. Whilst the case is being transported to obtain surgical assistance nothing is given by the mouth, though an injection of morphia is an advantage.

S. Maynard Smith.

HABIT SPASMS IN CHILDHOOD.—(See **TICS**.)

HÆMATEMESIS.—Vomiting of blood is a symptom occurring under various conditions, which should be differentiated as far as possible. Thus it may occur from (1) The rupture of a varicose vein in the œsophagus in cirrhosis of the liver; (2) The erosion of a vessel in ulcer of the stomach; (3) Bleeding of a cancerous growth in the stomach; (4) A simple fissure or erosion of the gastric mucous membrane, without ulcer; (5) Simple oozing from the mucous membranes, without any discoverable bleeding point, such as may be seen in cirrhosis of the liver, and in so-called gouty and hysterical hæmatemesis.

The general treatment is complete rest, an ice-bag to the epigastrium, a hypodermic injection of morphia ($\frac{1}{6}$ to $\frac{1}{3}$ gr.), and the prohibition of all food by the mouth; small pieces of ice may be given to suck, but it is doubtful if this does good, and it may increase the thirst. Where the hæmorrhage persists, a hypodermic injection of 20 to 30 c.c. of freshly prepared sterile rabbit-serum may be tried. Nutriment must be administered by rectal enemata, but these need not be continued for more than three days after the hæmorrhage has ceased. Blood should be looked for in the stools after the vomiting has stopped, as minor degrees of bleeding may only show themselves in this way. Surgical intervention should be considered where hæmatemesis or melæna is recurrent or persistent; but owing to the difficulty of diagnosis, surgeons are often unwilling to intervene, and in the vast majority of cases where the bleeding comes from the stomach,

the hæmorrhage ceases under the means above indicated. In bleeding from a duodenal ulcer (see also GASTRIC ULCER) there is much to be said for the prompt performance of gastro-enterostomy. After the bleeding has been checked, and oral feeding resumed, we may give iron as a hæmostatic as well as a hæmatinic remedy.

R Tincturæ Ferri Perchloridi		Aquam	ad ʒj
Glycerini	āā ℥x		

Two tablespoonfuls every four hours.

Or if there be constipation :—

R Ferri et Alumini Sulphatis	gr v	Acidi Sulphurici Diluti	℥xij
Magnesii Sulphatis	gr xl	Aquam Menthæ Piperitæ	ad ʒj

Two tablespoonfuls three times a day.

The diet should be at first cold, bland, and of soft consistence, but in the course of a week the patient may revert to his former food. (See also GASTRIC ULCER and GASTROSTAXIS.)

Robert Saundby.

HÆMATURIA.—Hæmaturia is a symptom of many diseases of the urinary organs. Before embarking upon the treatment, it is necessary to diagnose the source and the cause of the hæmorrhage. A short note will therefore be made as to the means of localization and diagnosis.

Localizing Symptoms.—The presence of one or more of the following symptoms points to the kidney as the source of the hæmorrhage :

Severe pain in one kidney, renal colic, tenderness of the kidney, enlargement of the kidney, blood well mixed throughout the urine and "smoky," long worm-like clots, the presence of tube casts and renal cells.

The following symptoms point to the bladder as the source : Pain at the end of the penis, suprapubic pain, frequent micturition, difficult micturition, bright blood in small quantity, initial or terminal hæmaturia, large irregular clots, the presence of bladder epithelium.

There are some fallacies in the symptomatology that may mislead the surgeon : Aching in one kidney may be caused by disease of the bladder, such as papilloma. Bilateral renal aching may be due to disease of the kidneys or to disease of the lower urinary tract. Frequent micturition may be reflexly caused by some diseases of the kidney when the bladder is healthy.

In many cases of hæmaturia there are no localizing symptoms. In these and in all cases where any doubt exists, the bladder should be examined with the cystoscope. By this means the source of the hæmorrhage will be localized to the bladder or the kidney, and if the former organ is the seat of disease, a diagnosis will be made.

Severe symptomless hæmaturia from the kidney is most frequently due to renal growths, or to subacute or chronic nephritis ; angioma of a renal papilla has been described. Other causes of renal hæmaturia usually accompanied by symptoms are injury, stone, pyelonephritis, and tuberculosis.

The most frequent cause of symptomless hæmaturia from the bladder is growth which may be simple or malignant.

Other causes of vesical hæmaturia accompanied by symptoms are : cystitis, tuberculous cystitis, stone, enlargement of the prostate.

Treatment of Renal Hæmaturia.—Hæmorrhage from the kidney necessitates in most cases operative measures for diagnosis or for treatment. Where operation is contra-indicated, or postponed, treatment by drugs becomes necessary. Opium is useful in cases of renal hæmorrhage of a surgical nature. It should be avoided where there is advanced disease of both kidneys, as there is a danger of causing suppression of urine.

Ergot may be given hypodermically as ergotin, or by mouth as the fluid extract. The results are frequently disappointing. Calcium lactate (10 to 15 gr. every four hours) is a more valuable drug. It may cause rapid cessation of a severe renal hæmorrhage. It should not be continued for longer than forty-eight hours.

The operative treatment in renal hæmaturia varies with the disease.

In renal growths nephrectomy should be performed whenever a diagnosis has been made, unless the growth be too advanced for radical treatment. Operation in some of these cases takes the form of an exploratory laparotomy, with a subsequent nephrectomy if the conditions are found suitable.

Conditions such as localized patches of nephritis, and angioma of a renal papilla, are diagnosed only on exploration of the kidney. Nephrotomy usually causes the hæmaturia from a patchy nephritis to cease, and the removal of the papilla has similarly cured hæmaturia due to angioma.

In *rupture of the kidney*, the side should be strapped and an ice-bag placed over the organ. Should the hæmorrhage continue, the kidney must be exposed and dealt with according to the conditions found. The hæmaturia of stone is treated by nephrolithotomy. In pyelonephritis with hæmaturia, nephrotomy should be performed, and usually suffices to relieve the symptoms; nephrectomy is sometimes necessary.

In *renal tuberculosis*, where nephrectomy is considered inadvisable, an attack of severe renal hæmorrhage may necessitate nephrotomy.

Drugs have even less effect on vesical than on renal hæmorrhage. Washing the bladder may become necessary in cases of hæmorrhage from growths or from enlargement of the prostate.

The patient should be recumbent. If the urethra is sensitive, 20 min. of novocain solution (4 per cent) should be instilled into the posterior urethra by means of a Guyon's syringe. A catheter of as large a size as the urethra will admit is gently passed into the bladder, and the bloody urine is withdrawn. The washing fluid may be introduced either from an irrigator raised two or three feet above the level of the patient, or by means of large glass hand syringes, and a large total quantity should be used. The best solution is weak nitrate of silver (1 in 10,000 or 15,000). The bladder should not be fully distended with the fluid, only a few ounces being run in and out at a time.

In persistent, slight bleeding without clotting, a continuous stream of this solution through a double-way catheter may be successful when other methods have failed.

Weak solutions of suprarenal extract are not very effective. Hæmorrhage will sometimes be stanchied by emptying the bladder and injecting half a drachm of strong solution of epinephrin (1 in 1000 or 2000) into the bladder, allowing it to remain for a few minutes, and then washing the bladder with boracic solution.

When clots are being formed, they block the eye of the catheter and interfere with washing. A large evacuating cannula, such as is used after litholapaxy, is very useful in such cases. The rubber evacuating bulb used for this operation may be used to suck out clots. If, however, large clots are forming, and especially if the bladder has become distended with clot, suprapubic cystotomy should be performed, the clots cleared out, and a copious stream of hot fluid passed through a catheter in the urethra and allowed to well up through the suprapubic opening. A large tube is retained in the suprapubic wound for four or five days and then removed.

The removal of growths of the bladder, of stone, and enlarged prostate are the radical methods of treatment of hæmaturia due to these conditions.

Cystitis may necessitate suprapubic drainage of the bladder. The results of operative measures on tuberculous ulceration of the bladder are very unsatisfactory, and washing the bladder is almost invariably followed by renewed activity of the disease. Hæmorrhage is never so profuse in these cases as to necessitate local interference.

J. W. Thomson Walker.

HÆMOGLOBINURIA.—(See BLACKWATER FEVER; RAYNAUD'S DISEASE.)

HÆMOPHILIA.—In the case of a family who are known to be bleeders, prophylactic measures are of importance. Children should be protected from injury as far as possible, and no surgical operation of any kind should be undertaken with the single exception of vaccination, which, if carefully performed, does not usually give rise to any trouble. If surgical procedure of any kind becomes absolutely necessary, the patient should be put on a course of chloride or lactate of calcium for a week or two before. It is often advised that the daughters of those families through whom the disease is transmitted should not marry, but this is a counsel of perfection which it is not always easy to carry out. Some family histories have recently been published in which the females and not the males have been affected, and in some of these the transmission has been through the male side of the house; while in at least one case there has been a reversal, the females having transmitted it in early generations, the males in later. As almost any injury, no matter how small, may cause fatal hæmorrhage in a bleeder, constant care and supervision may be required in cases which are known to be extreme, for all are not equally prone to serious hæmorrhage. A blow on a joint, for example, may cause serious hæmorrhage into it; or if elsewhere on the limb, there may be a great deal of subcutaneous bleeding. Such lesions are best treated by compression and complete rest.

Actual hæmorrhage may be traumatic or spontaneous. The latter is almost always from the mucous surfaces. In the former case, the patient must be kept at rest, and pressure on the bleeding point is the most useful procedure. Styptics, such as iron and epinephrin, may be tried, but are very often only temporarily of service. The application of cold, either by ice or ethyl chloride, is sometimes useful. A 5 per cent solution of gelatin has been tried, both locally and by subcutaneous injection, but has rather fallen out of use, as toxic symptoms have followed its employment, and disaster from imperfect sterilization. Chloride of calcium may be given internally, and applied locally also. Spontaneous hæmorrhages are very often preceded by a sensation of well-being, and when this sensation is experienced it seems to be worth while to let the patient take a mild saline purgative. When the hæmorrhage occurs, if the bleeding point can be reached, the same local applications should be made as in traumatic hæmorrhage. Chloride of calcium has been advocated because of its tendency to increase the coagulating power of the blood, which is so markedly deficient in hæmophilia. It is very doubtful whether a sufficient amount of lime can be added to the blood to affect coagulation. It may be given in large doses (15 to 30 gr.) by the mouth, three times a day, and this may, if necessary, be supplemented by its use per rectum in doses of 60 gr. in solution. The great disadvantages of this drug, however, are its tendency to upset the digestion, and its nauseous taste. It should, therefore, only be pushed in large doses when there is urgent need for it. When given, as it sometimes may be, in short courses to anticipate bleeding, the dose should be much smaller. Lactate of calcium, in doses of 20 to 60 gr., has been advocated instead of the chloride, alone or with equal quantities of magnesium carbonate. It seems to be as efficacious, and has the advantage that it does not upset the digestion. It should be given an hour before meals. Other internal styptics may of course be tried, such as ergot, turpentine, hamamelis, and epinephrin, but too often they all fail in turn. The best results, in my experience, are obtained from serum treatment. Fresh serum from the horse, rabbit, or man may be used, but not ox serum, as it may cause headache, vomiting, rigors, and cyanosis. The serum may be given by the mouth, but is more useful when administered hypodermically or intravenously. The last method is best in those severe cases in which a hypodermic injection gives rise to a hæmatoma. The dose is 20 to 30 c.c. hypodermically, or 10 to 20 c.c. intravenously—correspondingly smaller doses are given to children. Fresh

serum is always best, but the normal horse serum prepared by manufacturing chemists is also useful if fresh serum cannot be obtained, and in an emergency ordinary antidiphtheritic serum may be used. The effect of serum injection lasts about a month, and I have succeeded in keeping patients free from hæmorrhage for many months by giving regular injections.*

Subcutaneous injection of 10 c.c. of a 5 per cent solution of Witte's peptone in 5 per cent salt solution, given every second day, has been recommended.

Loose clots should always be removed from a wound or bleeding surface, and bleeding surfaces should be soaked with a strong solution of thrombokinase in the form of an extract of lymph-gland or thymus, or even with fresh human blood from another person.

After a hæmorrhage the patient is naturally very much reduced, and will usually require rest, iron, and general tonic treatment. In some cases the tendency to bleeding diminishes later in life.

G. Lovell Gulland.

HÆMOPHTYSIS.—The cause of the bleeding must be first determined. In the larger proportion of cases it is an incident in the course of pulmonary tuberculosis. It also frequently occurs in other congestive conditions of the lung, notably passive congestion associated with mitral stenosis. Less frequent causes are bronchiectasis, pulmonary gangrene, malignant disease, hydatids, syphilis, pulmonary embolism or thrombosis, and atheroma (aneurysm). It may occur in relation to various morbid blood conditions, and is sometimes apparently dependent upon menstrual irregularity. Vicarious menstruation—it may be supplementary menstruation—certainly occurs.

Where there is reasonable ground for doubt as to the origin of the bleeding, it is a safe rule, from the point of view of treatment, to regard it as most probably a manifestation of tuberculous involvement. Occurring in pulmonary tuberculosis, it varies both in origin and clinical manifestation. Thus, in the early stage, it may simply be an expression of capillary oozing from a congested area. This is relatively unimportant. Later on, it is more likely due to ulceration of a considerable branch, or rupture of an aneurysmal dilatation of a vessel in relation to a vomica. This is more serious, and may prove fatal.

All cases of hæmoptysis do not require special treatment. Thus, in mitral stenosis, assuming that the primary condition has been attended to, e.g., by digitalis, the hæmorrhage may be actually beneficial, and is best left alone. Attempts to stay it may be positively unwise. Nature's attempt at depletion should be rather encouraged, e.g., by the application of a leech or cup over the base of the lungs. In rupture of an aneurysm of the aorta, treatment is of little avail.

In slighter degrees of bleeding in pulmonary tuberculosis—mere coloration of the expectoration—little need be done beyond insistence on hyperaeration and other hygienic measures. It is remarkable how seldom bleeding recurs when open-air measures are sufficiently carried out. (See PULMONARY TUBERCULOSIS.)

When the bleeding is considerable, the main indications are to calm the patient and promote clotting within the vessel by quieting the excited circulation and gently lowering pulmonary blood-pressure.

The first thing to be done in most cases is to reassure the patient and his friends. The patient's fears will be best allayed by his knowing that the bleeding is not generally dangerous. Thereby his disturbed circulation becomes steadied. Without fuss, he should be kept as quiet as possible. He should not be allowed to speak, and the fewer friends about him the better. The room should be as fresh and cool as possible, and the patient's clothing light. If necessary, the feet can be kept warm by hot bottles.

* The danger of inducing anaphylactic shock should not be overlooked.—AMERICAN EDITOR.

The recumbent posture should be maintained, with the head more or less raised. The patient usually assumes the position which allows of freest discharge of the blood from the air-passages. Theoretically, it is better that he lie on the side which is the seat of bleeding. Thereby the blood is less likely to pass into and block the bronchial passages of the other side. When the side is known, the patient's position may be arranged accordingly. It is a mistake, however, to examine him much for the determination of this.

He should not be bothered with food, which, for the first twenty-four hours, may be reduced to a minimum. He will not suffer from starvation. What food is given may take the form of milk, which may be iced, or of meat jellies. Alcohol should be excluded. Thirst, which is sometimes marked, may be assuaged by the use of iced lemon and water, or dilute sulphuric acid in water. This is generally better than sucking simple ice, which is apt to disturb the stomach.

As soon as possible an opiate should be administered—say morphine $\frac{1}{4}$ to $\frac{1}{2}$ gr. This has the double advantage of calming the patient's excitement—perhaps sending him into a gentle sleep—and restraining cough. The latter effect is most important, as repeated cough, by shaking the bleeding vessel, tends to prevent coagulation. In presence of persistent or recurrent bleeding, the regular exhibition of sedatives is on this account indicated. Except in very profuse hæmorrhage, opium may be given freely. Sometimes the addition to the morphine of atropine, $\frac{1}{100}$ gr., is of value. The combination of digitalis, $\frac{1}{4}$ to $\frac{1}{2}$ gr., with opium may be helpful, even although the significance of digitalis has been questioned because of its usual action in increasing blood-pressure.

To lower blood-pressure, the use of circulatory depressants is desirable. From this point of view ipecacuanha is most serviceable. The writer's experience is much in favour of this plan of treatment. Ipecacuanha should be given in comparatively small doses, say 5 gr., repeated every one or two hours. It is not necessary or desirable to produce emetic effects. The combination of ipecacuanha with opium, as in Dover's powder, 5 gr., repeated similarly, will be found efficient.

Small doses of mercury are of excellent service, and may be exhibited along with ipecacuanha and opium, as in the following formula, which the writer strongly recommends :—

R Pulveris Ipecacuanhæ et Opii gr iv | Hydrargyri cum Creta gr j
For use every two to four hours while bleeding continues.

It is sometimes advisable to give a larger dose of calomel—say 5 gr. at once.

From the same point of view, the inhalation of amyl nitrite may prove serviceable in patients with a tendency to recurrent bleeding of large amount. It may be wise to let the patient carry about capsules of the drug. Its use should be restricted to severe bleeding, more particularly where the blood-pressure is definitely high. To meet the tendency to slighter hæmorrhages in presence of sustained high pressure, the more continuous use of small doses of nitroglycerin, or nitrite of sodium, may be serviceable.

The patient may advantageously take a saline purge, say magnesium sulphate or sodium sulphate, either singly or combined (1 to 2 drachms). This may be repeated several times, at intervals of three hours. Where the blood-pressure is unusually high, $\frac{1}{2}$ -minim doses of tincture of aconite, repeated every hour for a few doses, may prove of the greatest value. Experimental observations go to show that aconite exerts an important influence in lowering pulmonary blood-pressure. Venesection has been proposed from the same point of view, but the number of cases in which this is necessary are extremely few.

If the bleeding be severe, the application of ice to the chest by means of an ice-bag may be allowed; as a rule it is not necessary or even desirable. The application of ice to other parts, for example over the external genitals, may sometimes prove advantageous. Tight bandaging of the thighs and upper arms, e.g., by means of Esmarch's tubing, has been practised, with a view to limiting the return of blood to the lungs. This may be worth trying in the graver fulminant cases, as when an aneurysmal dilatation has given way; generally it is unnecessary.

Numerous other drugs have been from time to time proposed, and some of these have obtained considerable reputation on insufficient and even doubtful grounds. Thus, ergot, which is still too largely used both by the mouth and subcutaneously, has little to recommend it. Experimentally it has been proved to lead to a rise in pulmonary blood-pressure, and the sum of clinical experience is against its use. Nor can suprarenal extract or its active principle, epinephrin, be recommended.

Various astringents have been favoured, e.g., gallic acid, tannin, and lead. They are probably valueless. Acetate of lead has been much praised in combination with opium. The probability is that the lead has little effect on the bleeding.

With the object of hastening coagulation, certain hæmostatic drugs have been proposed, more especially chloride of calcium, or lactate of calcium (pleasanter to take), 10 to 20 gr., thrice daily. Satisfactory results are frequently obtained.

Of other hæmostatics, turpentine and its congeners terebene and terpene, and eucalyptol in large doses, are sometimes of service. The repeated use of small doses of terebene, 5 to 10 min., or 3 gr. of terpene hydrate three times a day, seems to reduce the tendency to recurrent bleeding. Tincture of hamamelis, (B.P.) 30 to 60 min., has been thought worthy of trial, although it is open to the same experimental objection as ergot. The old-fashioned domestic remedy of common salt, 1 or 2 teaspoonfuls, may be used when other agents are not available.

After acuter manifestations have disappeared, the patient must be careful of himself in a number of ways. He should be kept at rest, as far as possible, till all blood-stained discharge has disappeared. The diet should continue simple and non-stimulating. Alcoholic liquors should remain excluded. Hæmatinics—iron and arsenic—should be given with caution, or not at all. The patient must avoid sudden effort and violent exercise, e.g., dancing, strained speaking, or singing. There must be no excess of any kind. Women should be especially careful in relation to the menstrual period, when sufficient physical rest should be insisted on. A mustard foot-bath may be advantageously used for a night or two before the menses are due. The bowels should be carefully regulated, so as to prevent constipation.

The treatment of the initial disease, more particularly pulmonary tuberculosis, must be carefully prosecuted on the lines discussed under the appropriate heading. (See also HEART, VALVULAR DISEASES OF, PULMONARY TUBERCULOSIS, etc.).

R. W. Philip.

HÆMORRHAGE, CEREBRAL.—(See APOPLEXY.)

HÆMORRHAGE, INTESTINAL.—(See DUODENAL ULCER.)

HÆMORRHAGE, INTRACRANIAL.—Hæmorrhage into the cranial cavity occurring as the result of injury may be classified according to the site of the extravasated blood. From the point of view of treatment, however, the chief

question to be determined is whether the blood is between the dura mater and the bone, or within the dura.

Extradural Hæmorrhage.—In the very great majority of cases the source of the blood is the anterior branch of the middle meningeal artery—occasionally it may be one of the venous sinuses or the posterior branch of the middle meningeal which bleeds. If, after the receipt of a blow on the head, the patient recovers consciousness, and then after an interval (usually less than an hour) symptoms of compression ensue—gradually increasing and steadily progressing to coma—extradural hæmorrhage may be diagnosed.

TREATMENT.—The general treatment needed is given under the heading of BRAIN, COMPRESSION OF. The chief essential, however, is the early localization of the site of the extravasation, in order that operative measures may be taken. In a patient, then, with the general symptoms of compression from extradural hæmorrhage, the following conditions are to be looked for :—

1. Where there is a scalp wound, a fissured fracture with blood welling from it may be seen crossing the line of the middle meningeal artery or of a venous sinus, and indicates injury to the vessel at that spot.

2. A hæmatoma developing in the temporal fossa suggests injury to the middle meningeal on that side.

3. Hemiplegic symptoms indicate the anterior branch of the middle meningeal artery of the opposite side as the source of the hæmorrhage.

4. Absence of hemiplegic signs suggests that one of the venous sinuses or the posterior branch of the middle meningeal artery is the source of the bleeding.

5. Protrusion of the eyeball with a widely dilated fixed pupil indicates that blood is finding its way round to the base of the skull, and that its probable origin is the anterior branch of the middle meningeal of the same side.

6. Where there is doubt, the history of the part struck and the presence of a bruise may add the diagnosis.

If it be decided that the *anterior branch of the middle meningeal artery* is the source of the hæmorrhage, a flap is turned down ; and if a fracture be found, a disc of bone is removed with the trephine where the line of fracture crosses the line of the artery. Should no fracture be detected, the pin of the trephine is placed upon a point $1\frac{1}{2}$ inches behind the external angular process of the frontal bone and $1\frac{1}{2}$ inches above the zygoma. The cranial cavity having been opened, the blood-clot between the bone and dura is washed away by a stream of hot sterilized saline solution. The bleeding artery is secured by passing a ligature around it, or by plugging the bony canal in which it lies with aseptic wax. A drainage tube is inserted and the wound closed.

If it be found that the blood comes from *one of the venous sinuses*, a trephine hole is made over the sinus and enlarged with Hoffman's forceps until the bleeding point is exposed. The hæmorrhage is then controlled by packing with strips of sterilized gauze, which are removed on the third day.

Intradural Hæmorrhage.—The symptoms will be those of concussion, rapidly merging into those of compression, usually without any return of consciousness. The extravasation of blood may be from one of the venous sinuses, but is usually dependent upon the rupture of vessels in a laceration of the brain. Intradural hæmorrhage often occurs in fractures of the base of the skull.

TREATMENT.—For the general treatment see BRAIN, COMPRESSION OF. Sometimes the site of the lesion may be localized by keeping a careful watch for the onset of spasm and rigidity in the muscles, of convulsions, and of paralysis. If so, the suspected area may be exposed. A flap of scalp is turned down, and the skull is opened with a trephine. The dura mater, if there be bleeding beneath, will bulge into the trephine hole and present a dark blue appearance. The dura

is incised, the clot turned out, and the bleeding vessels are secured, if possible, with ligatures; otherwise the source of the bleeding, should it be accessible, is packed with sterilized gauze.

More frequently, however, the symptoms are those of generalized compression, and are due to extensive basal extravasations. If the symptoms of compression are slight, and are limited to drowsiness and restlessness with slight slowing of the pulse and raising of blood-pressure, treatment may be expectant. But if symptoms are severe from the start, or increasing in severity, no time is to be lost before opening the skull. The best chance of saving the patient lies in a rapidly performed decompression operation. A flap is turned down in the temporal region on the suspected side. The temporal fascia and muscle are divided in the direction of their fibres, and with a trephine and forceps an area of bone is removed about $1\frac{1}{2}$ inches in diameter. The dura is opened and clot turned out. The brain is gently lifted to liberate any basal collections, and rubber drainage strips inserted. The fascia, muscle, and skin are closed in layers. Both sides must be opened if a unilateral operation fails to give relief.

S. Maynard Smith.

HÆMORRHAGE, UTERINE.

1.—ANTE-PARTUM HÆMORRHAGE.

Severe ante-partum hæmorrhage is nearly always due to partial separation of the placenta. There are two main varieties: (1) *Accidental Hæmorrhage*, (a) External, (b) Internal or concealed; (2) *Unavoidable Hæmorrhage*.

1. **Accidental Hæmorrhage.**—By this is meant bleeding which results from the partial detachment of a normally implanted placenta. Most commonly the blood escapes externally, though in rare cases it is retained in the uterus.

Accidental hæmorrhage sometimes follows excessive exertion, a blow, or fall, but frequently there is no obvious exciting cause. It may occur at any time during the last three months of pregnancy. If the bleeding be slight, and it is perfectly certain that the placenta is not in the lower uterine segment, the patient may be treated by rest in bed and small doses of ergot. If the hæmorrhage be profuse, or has been repeated, labour must be induced if it has not already set in. In most cases of accidental hæmorrhage where there have been one or more free losses of blood, labour comes on spontaneously, though the pains when the patient is seen may be feeble and infrequent. The object of treatment in these cases is to excite vigorous labour pains. The blood is coming from the upper active uterine segment, and the bleeding is nearly always controlled when labour properly commences. The rupture of the membranes and the application of a firm binder usually achieve this object. The introduction of a bougie into the uterus to stimulate uterine action is sometimes advantageous. When vigorous labour pains have been induced, there is little or no fear of further hæmorrhage. Firm plugging of the vagina has been advocated. The value of this method probably depends largely on the fact that this also excites labour pains. Avoid violent or hasty methods of delivery. There is no cause for hurry when labour has once set in.

In cases of extensive concealed hæmorrhage, where the cervix is sufficiently dilated it is a good plan to perform version and bring down the half breech. In severe cases where, owing to the condition of the cervical canal, version is impossible, Cæsarean section has been advised. If possible the blood which has accumulated in the uterus should be allowed to escape, as the presence there of a large quantity of blood interferes with vigorous contractions. Concealed accidental hæmorrhage is a very dangerous condition, and one that not infrequently proves fatal. It is fortunately rare.

2. **Unavoidable Hæmorrhage.**—By this is meant the hæmorrhage which is due

to the partial detachment of a placenta situated in the lower uterine segment. When the placenta is prævia, partial separation of it, and consequently hæmorrhage, will inevitably occur with the onset of labour pains, and will be liable to continue at intervals during the whole of the first stage of labour. Labour may not set in until full term, but it is not rare for hæmorrhage to occur some weeks earlier. If in such a case nothing is done, repeated floodings will occur, and the patient may be reduced to a condition of profound anæmia before labour definitely begins. Whenever placenta prævia is diagnosed, labour must be induced, as hæmorrhage is certain to recur.

When the placenta is situated centrally over the os internum, the mother is placed in a position of grave danger. Probably, if the surroundings permitted it, delivery by Cæsarean section would be the safest and best method of treatment.

More commonly, although the placenta covers the os internum, the membranes can be reached. If labour has not set in, or the cervix is only slightly dilated, it is advisable to introduce one or more laminaria tents into the cervix, and these should be retained in position by a firm vaginal plug. At the end of six or eight hours the plug and tents may be removed. By this time the cervical canal will probably have been taken up and the os will be dilated sufficiently to admit two or more fingers. As soon as this is the case, bipolar version should be performed, and the half breech of the child drawn firmly down so as to exert continuous pressure against the lower uterine segment and bleeding area during the rest of the stage of dilatation. With the termination of the first stage, the danger of further bleeding has passed by if the presenting part descends freely. There is no necessity to hasten the extraction of the child after version has been performed. If much hæmorrhage has already occurred, there is great likelihood of the development of symptoms of shock if the child be too speedily delivered. Pressure on the bleeding area may be maintained by means of a Champetier de Ribes' bag, and this may be employed instead of version when the os is the size of half a crown. On the whole, probably the half breech of the child is a more effective means of maintaining pressure than the bag, and if a bag is used the patient is liable to bleed when it comes away, unless the presenting part rapidly descends of its own accord or is brought down artificially. In cases of partial placenta prævia, where the patient is in labour and the os is already half dilated, if the tissues of the cervix are soft, manual dilatation and extraction by forceps may be employed.

In cases of placenta prævia the child is frequently still-born.

II.—POST-PARTUM HÆMORRHAGE.

This term is applied to cases of excessive bleeding after child-birth. It may be more accurately defined as a loss of twenty ounces or more, or of a sufficient amount to induce symptoms of loss of blood.

In the majority of cases the bleeding occurs from the placental site, and is due to uterine inertia. In other cases the blood comes from a deep tear of some part of the genital tract. Bleeding from both these sources at the same time may sometimes be met with. Hæmorrhage from a tear may generally be readily diagnosed by the fact that in these circumstances the uterus is found to be firmly contracted.

The treatment of the two conditions is obviously different.

1. **Hæmorrhage from the Placental Site.**—The object of treatment in this case is to excite efficient contraction and retraction of the uterus. If the placenta has not yet come away, the first thing to do is to endeavour to express it, after having excited a contraction by kneading it. If this cannot be done, the placenta must be removed by the hand introduced into the uterine cavity.

When the uterus is empty, the ordinary methods of exciting contraction and retraction, and thus checking the bleeding, are : (a) Kneading the uterus by the hand on the abdomen ; (b) Irrigation of the uterus with hot water ; (c) The administration of ergot.

To knead the uterus efficiently, the fingers of the left hand should be placed behind the fundus, and the thumb in front. By movements of friction and squeezing between the fingers and thumb a contraction can generally be excited. If relaxation and further bleeding occur, the uterus may be irrigated with hot water at a temperature of 118° F. This is best introduced into the uterine cavity by means of a long tube and irrigating apparatus. Plenty of hot water is required. If a thermometer is not to be obtained, the heat of the water may be fairly accurately ascertained by means of the hand. Water at a temperature of 118° F. feels uncomfortably hot, though not too hot to permit the hand being held in it. To avoid the mischance of scalding the patient, the water should always be tested in this manner by thrusting the hand deeply into the douche can, as in the hurry of the moment the temperature registered by the thermometer may be inaccurately read by the nurse. An injection of ergotine into the buttock should be given, provided that the placenta has come away or been removed.

These methods of treatment, separately or in combination, check nearly all cases of post-partum hæmorrhage due to uterine inertia. In exceptional cases they may prove insufficient. In such circumstances there are two other plans of treatment that may be employed. These are :—

a. Introduce the hand into the uterus and clear out all clots or fragments of retained placenta or chorion. Then clench the hand, and knead the uterus over it with the other hand on the abdomen. When a contraction has been excited, express the internal hand slowly from the uterine cavity.

b. Bi-manual compression. Introduce the left hand into the vagina if the patient is lying on her left side, or the right one if she is lying on her back. Clench the fingers. With the external hand, antevert the uterus and press it down on the internal hand, which generally lies in front of the cervix. Such pressure need not be very forcible, but it may be maintained if necessary for half an hour or more. Be sure that the uterus is emptied before bi-manual compression is employed.

Compression of the abdominal aorta has been advocated in some cases where the bleeding is unusually profuse and sudden.

2. Hæmorrhage from Tears.—Tears which cause free external bleeding are nearly always situated either in the cervix or at the vaginal orifice.

A tear of the vaginal portion of the cervix does not usually cause much bleeding. If, however, it extends deeply into the supravaginal portion, it may cause great bleeding. Such tears almost always occur laterally.

Tears at the vaginal orifice may be either anterior or posterior. The anterior tear extends into the vestibule, a vascular area at the side of the urethra. A posterior tear (perineal tear) is very common, but only in rare instances does it lead to serious bleeding.

Bleeding from lacerations is best treated by bringing the torn surfaces into apposition by deep sutures. The cervix can be easily sutured if it be first brought down by a volsella. Bleeding from the perineum or vestibule can be stopped in a similar manner, and can be temporarily checked by pressing a pad of cotton-wool firmly against the bleeding area so as to compress it between the pad and the adjacent bone. If the bleeding comes from the cervix, and it is not practicable to suture it, hot vaginal injections may be tried, and if these fail the vagina may be firmly plugged. This must never be done unless the uterus is firmly contracted.

Perchloride of iron in any form should never be used to control post-partum hæmorrhage.

W. J. Gow.

HÆMORRHOIDS.

External Piles.—These small swellings at the anal margin often cause a considerable amount of pain and discomfort, especially when swollen and inflamed, and the patient is obliged to lie up. As a rule the swelling and inflammation subside in a few days, but a recurrence of the condition is common, and some patients are very subject to these acute attacks. One of the most important factors in the treatment of external piles is to ensure cleanliness of the part. The patient should not use paper as a detergent, but wash the parts with warm water and a soft sponge, afterwards dusting them with boracic powder.

A mild aperient should be given, and if there is much swelling, the patient should remain in bed and have hot fomentations applied. The following ointment applied to the swellings on a piece of lint will often effectually allay the pain :—

R Morphinæ Sulphatis	gr x	Unguenti Stramonii	āā 3j
Unguenti Belladonnæ			

The most effectual method of treatment, and at the same time the best if it can be carried out, is to remove these external piles at once. This immediately gets rid of the pain, and materially shortens the time before the patient is well again. The parts should be rendered as surgically clean as possible, and then each swelling rendered anæsthetic by the injection of cocaine at its base. The greater part of each swelling should then be cut away with sharp scissors, the parts dusted over with an antiseptic powder, and a pad of antiseptic dressing firmly applied with a T bandage. On no account should a ligature ever be tied round these external piles, as the results are most disastrous, the patient suffering acute pain. A ligature is quite unnecessary, as hæmorrhage is easily controlled by pressure. Quite apart from their being inflamed, many patients suffer considerable discomfort from them, and when this is the case an operation for their removal is advisable.

Internal Piles.—The treatment may be divided into palliative and operative measures.

Palliative treatment is often all that is required in the milder cases, and if properly carried out may give most satisfactory results. This treatment consists in keeping the bowels regular, in correcting the diet, and in the local application of sedatives and astringents. Small doses of cascara combined with a morning dose of salts, or the confection of senna at bedtime, are useful. Drastic purgatives are harmful. The diet should be simple, and alcohol is better avoided, as also are coffee and strong tea. Moderate exercise, especially walking, is often most beneficial. Sitz baths several times a week are often of great service, and those who can afford it can have a sitz douche fitted in the bath-room which may be used daily. Much benefit is often derived from the use of hot or cold water injections into the bowel night and morning. For this purpose an eight-ounce rectal bulb syringe is much better than the ordinary Higginson's syringe. The water should be as warm as can be comfortably borne, or else quite cold, and some hazeline or alum may with advantage be added to it. A good injection is witch hazel 2 dr., water 2 oz.

If there is any prolapse of the piles, the patient should be instructed to immediately replace them, and care should be taken to see that they do not get rubbed by the clothing.

All ointments to be used in the rectum should be prescribed in collapsible tubes to which a bone rectal nozzle can be screwed, or should be used with an

ointment introducer, and should be made up with vaseline and not lard. The following ointment is often useful :—

R Unguenti Acidi Tannici	Unguenti Belladonnæ	3ā 3ss
Unguenti Stramonii (10% of extract)		
M. ft. ung. A little of this ointment to be squeezed into the bowel night and morning.		

Hazeline ointment is also useful, and great benefit often follows the use of ointments or suppositories made up with epinephrin. It is not advisable, however, to use epinephrin compounds for long periods, recent researches having shown that they cause damage to the kidneys.

R Extracti Suprarenalis	3ij	Unguenti Lanolini	3vj
	M.		
R Acidi Tannici	gr xxx	Adipis Benzoati	3j
	M. ft. ung.		

Suppositories are much preferred by some patients on account of their convenience. The following will be found useful :—

R Ichthyolis		Extracti Stramonii	gr ½
Acidi Tannici	3ā gr v	Extracti Hamamelidis	gr x
Extracti Belladonnæ	gr ½		
	M. ft. supposit.		
R Extracti Suprarenalis	3ij	Olei Theobromatis	3iv
	M. ft. supposit.		

The following mixture taken by the mouth is often useful in alleviating the pain and discomfort of bleeding and prolapsing piles :—

R Pulveris Cretæ Aromatici (B.P.)	gr xx	Decoetum Hamatoxyli (B.P.)	ad 3j
Tincturæ Catechu (B.P.)	3j		

When, however, bleeding and prolapse of the piles are frequent, palliative measures offer only temporary benefit, and a cure of the condition cannot be expected apart from operation. It is a mistake to advise such patients to try palliative treatment for long periods, as thereby they suffer much pain and discomfort, and ultimately an operation is necessary, which if performed earlier would have saved them great inconvenience.

Indications for Operation.—(1) Repeated hæmorrhages ; (2) Prolapse of the piles ; (3) Pain and discomfort ; (4) Failure of palliative treatment ; (5) Patient going to reside in a hot climate ; (6) If the patient is unduly worried as to his rectal condition.

OPERATIVE TREATMENT.—*Stretching the Sphincter* is suitable only in slight cases.

Injections of Carbolic Acid into the Piles are not to be recommended except in cases where a general anæsthetic is contra-indicated. The procedure consists in injecting each pile with a 10 per cent solution of carbolic acid in glycerin and water. From 1 to 4 min. of the solution is injected with a special syringe into the centre of each pile, not more than one or two piles being treated at a time. The piles swell up and then undergo fibrous change, being, in a successful case, converted into scars.

The Ligature Operation still remains by far the best all-round operation for piles (*Fig. 33*), and should be the only one performed, except by experts. The preparation of the patient is a most essential part of the operation, and should occupy two days. He should first be given a full dose of castor oil, and next day a dose of salts. After the bowels have been well opened, the diet should be restricted to food which will leave little or no residue. On the night prior to operation a soap-and-water enema should be given, and at the same time a dose of catechu mixture containing 7 min. of tincture of opium, or a 10-gr. Dover's powder. The next morning nothing except a cup of tea must be given, and an enema of plain water should be administered four hours before the

operation. About an hour before operation 7 min. of tinct. opii, or another Dover's powder, should be administered. The parts should not be shaved, but should be thoroughly cleaned up in the usual way with antiseptics, preferably lysol 2 dr. to the pint. On no account should the bowel be washed out with strong antiseptics. The anæsthetic should be ether.

THE OPERATION.—When the patient is fully anæsthetized, the sphincters should be slowly stretched till the piles come well into view. The lower part of the rectum should then with swabs be washed out with soap and water, and lastly with weak lysol or other antiseptics. Pain after the operation is usually due to infection of the wounds, and consequent inflammation. It can be prevented entirely by careful attention to obtaining surgical cleanliness of the parts. Each pile which it is proposed to remove should be seized with forceps at its tip so that it can be pulled down. Taking the lowest pile first, a cut with a pair of scissors should be made so as to separate the pile from its attachment below to the rectal wall (*Fig. 33*). Into the cut thus made a stout plaited silk ligature is inserted, and, the pile being dragged down by an assistant, the ligature is firmly

Fig. 33.—To illustrate the Ligature Operation for Internal Piles.

tied round the pedicle that is left after separating the pile. Each pile is treated in a similar manner. The piles should not be cut off—though if very large a portion can be removed. The ligatures are cut long enough to protrude from the anus, and the wounds dressed by smearing them over with sterilized vaseline. Dressings and a bandage are then applied.

AFTER-TREATMENT.—No opium should be given after the operation unless there be pain, when a hypodermic injection of morphia is indicated. The dressing should be removed twice a day and the external parts douched with 1–40 carbolic. On the third or fourth day an ounce of castor oil should be given the first thing in the morning, and the bowels well opened. After the bowels have acted, the external parts must be well douched and then dressed with boracic powder or sterilized ointment. The bowels should then be kept acting easily each day with liquorice powder or salts.

If there be any external swelling, the patient should sit in a warm bath for twenty minutes once or twice daily. He must remain in bed till all the ligatures

have separated and come away, which will be in from eight to twelve days; and for a week after this he should not walk about.

The success of the operation and the comfort of the patient depend very largely on performing the operation as antiseptically as possible and preventing the wounds from being infected during the first forty-eight hours.

On no account must a ligature be placed round any external pile or portion of skin, as extreme pain will result. Skin tags or external piles should simply be cut off and not ligatured.

Excision is performed by cutting off the pile flush with the mucous membrane, and sewing up the resulting wound with catgut. There are several methods of suturing the wound, but the most important factor in obtaining success by this method is to thoroughly cleanse the rectum, and obtain aseptic healing in the wounds. There should be no pain after this operation.

While there are numerous methods described of excising piles, with immediate suture of the wounds, none of these operations give as good results as the ligature operation, failure and recurrence of the piles being not uncommon events.

Clamp and Cautery.—This consists in clamping each pile in turn, cutting off the pile in front of the clamp, and cauterizing the stump. The cauterization should be done with a Paquelin cautery-blade of fair size and at a dull red heat. Thorough burning of the stump is necessary, and the clamp should not be removed for a full minute after the burning is complete, or hæmorrhage is liable to occur. This method is best suited to cases where not more than three piles are present. It is inferior to the ligature operation, but gives good results if properly performed.

Whitehead's operation, which consists in excising the last inch-and-a-half of the rectal mucous membrane, has nothing to recommend it; and in view of the serious results which may follow, it should not be performed for uncomplicated piles.

J. P. Lockhart Mummery.

HAIR, DISEASES OF.

Baldness.—Alopecia arcata is discussed elsewhere (p. 18.) The treatment of premature fall of the hair demands consideration of the general condition of the patient and of the state of the scalp. No internal treatment has a specific action on the growth of the hair; but in many cases general tonics, such as arsenic, strychnine, and iron, are found to be of benefit.

Loss of hair frequently occurs during, and as a sequel of, acute illnesses, and especially of the exanthemata. In the later months of pregnancy and after parturition it is not uncommon. In all of these conditions seborrhœa is often present. The administration of general tonics, change of air during convalescence, and the local application of stimulating lotions containing cantharides, with resorcin and salicylic acid to combat the seborrhœa, are usually efficient. The prognosis is generally good. Syphilis is an important cause of the fall of hair, and in the secondary stage it is one of the commonest phenomena of the disease, and yields to the treatment directed to the destruction of the spirochætes. Seborrhœa occurs frequently as a sequel of syphilis, and demands the local treatment indicated in that condition. The loss of hair in myxœdema is symptomatic, and yields to thyroid treatment.

Cicatricial alopecia, the result of burns, suppuration, lupus vulgaris, lupus erythematosus, syphilitic ulceration, etc., is permanent where the hair follicles are destroyed.

The commonest cause of the early loss of hair, both in men and women, is seborrhœa. Prevention is easier than cure, and attention to early seborrhœa capitis will prevent many cases of premature baldness. Even when the hair

has begun to fall, measures directed to the cure of the seborrhœic process may be efficacious (see SEBORRHŒA). The most satisfactory applications in these conditions contain resorcin and euresol (a monoacetate of resorcin), salicylic acid, sulphur, and tars. In some cases mercurial salts are also of service. Where the scalp is dry the addition of a little ol. ricini is advisable; if there is excess of oil, some solvent of fats such as acetone is of service. Useful formulæ are the following :—

R Hydrargyri Perchloridi	gr j-ij	Olei Ricini	℥ss-j
Euresolis	℥j	Alcoholis	ad ℥iv
Acidi Formici	℥xx		
R Resorcini	℥j	Olei Ricini	℥ss
Quininae Sulphatis	gr xv	Alcoholis	ad ℥iv

Resorcin should not be used when the hair is very fair or white, as it tends to darken the tint; salicylic acid may then be substituted. If the fall of hair is associated with oily seborrhœa, the castor oil is omitted and acetone introduced thus :—

R Resorcini	℥iss	Acetoni	℥j
Hydrargyri Perchloridi	gr iss	Alcoholis	ad ℥vj

The more stimulating preparations containing cantharides and essential oils should be reserved for cases in which there is no tendency to seborrhœic dermatitis. The following formula is useful :—

R Tincturæ Cantharidis (B.P. 1898)	℥ij	Spiritus Rosmarini	℥j
Acidi Acetici Fortis	℥j	Aquam Rosæ	ad ℥viij
Glycerini	℥iv		

Pilocarpine has many supporters, and the following formulæ are recommended by Brocq :—

R Tincturæ Jaborandi (B.P. 1898)		Linimenti Saponis	℥iv
Tincturæ Cantharidis (B.P. 1898)	aa ℥j		

To be well shaken and applied once a day.

R Pilocarpinae Hydrochloridi	gr viij	Tincturæ Cantharidis (B.P. 1898)	
Olei Santalis		Spiritus Sacchari	
Olei Gaultheriæ	aa ℥x	Spiritus Camphoræ	aa ℥iv
Glycerini		Alcoholis	ad ℥v

Ointments are often more useful than lotions, especially in the seborrhœic cases, and a useful formula is the following :—

R Acidi Salicylici	gr x	Sulphuris Præcipitati	℥j
Beta-naphtholis	gr xx	Vaselinum	ad ℥j

Tars are also of service, and anthrasol colourless tar, in the proportion of a drachm to an ounce of vaseline and lanolin, may be tried. Shampooing of the scalp at regular intervals is necessary, and in cases where greasy preparations are used it may be required once a week. Nothing is better than Hebra's solution of soft soap and spirit, with the addition of a mild antiseptic such as thymol :—

R Thymolis	gr. xl	Saponis Viridis	℥ij
Alcoholis	℥ij		

Massage of the scalp, and high-frequency applications or the faradic brush, may also be found of value in improving the nutrition of the scalp by developing temporary hyperæmia.

Canities.—Very little can be done for this condition. No local treatment has any effect upon the pigmentation of the hair. Where there has been some debilitating illness or nervous condition, the internal administration of tonics, such as arsenic and nux vomica, may be tried.

Hirsuties.—The removal of superfluous hair is best effected by electrolysis.

For details of treatment *vide* ELECTROTHERAPEUTICS. In some extreme cases I have used repeated applications of the x rays, with a screen of aluminium 0.2 mm. in thickness. The sittings are given at intervals of six weeks at first, and later, intervals of three months or longer may be required. The possibility of cutaneous atrophy following this treatment must be explained to the patient, and I advise having a written indemnity. *James H. Sequeira.*

HALLUX RIGIDUS.—This is an affection of adolescents, and only rarely of children. It consists of a progressive stiffening and flexion at the metatarso-phalangeal joint of the big toe. The flexion may extend to 45° or 50° , and while it is sometimes accompanied by extension of the second phalanx, it is usually rigid in the straight position. Pain is at first complained of after walking or whenever forcible extension is made at the toe. The patient consequently walks with a stiff foot, and no effort is made to extend the metatarso-phalangeal range. Antero-posterior pressure of the joint is usually painless, while lateral pressure is very painful. In the later stages, the joint is considerably swollen, but the bone itself rarely participates. A yielding of both the longitudinal and transverse arches is generally present. Pathological investigation reveals in many cases lipping of the head of the first metatarsal and hyperæmia of the joint.

TREATMENT.—In the early stages this should consist of rest and hyperextension of the toe. Either with or without an anæsthetic, the joint should be fixed in such a position that walking no longer strains it, and a bar should be placed across the boot posteriorly to the metatarso-phalangeal range. This bar will allow the patient to walk without straining his joint, and combines rest of the tender area with locomotion.

In certain cases accompanied by painful flat-foot the heel of the boot should be elongated and raised on the inner side. The bar across the sole should also be raised on the same side. This deviates the body weight from the inner to the outer side of the tarsus and relieves the painful area.

In a large proportion of cases, operation is the only effective procedure. The head of the metatarsal should be freely removed, along with $\frac{1}{4}$ to $\frac{1}{2}$ inch of the neck. On no account should the joint be resected, as ankylosis may result. The operation is generally most successful.

Robert Jones.

HALLUX VALGUS and BUNION.—Hallux valgus is a deformity in which the first metatarsal bone turns in and the great toe turns out. It is a partial dislocation of the phalanx upon the metatarsal. In consequence, the sharp adducted inner condyle presses upon the skin, and gives rise to the prominent joint. A bursa in consequence forms beneath the skin, often accompanied by a hard corn, and this, in common with the irritated skin, is designated a bunion. This bursa is frequently the seat of inflammation, and therefore in time becomes much thickened. In exceptional circumstances the inflammation may resolve in suppuration, accompanied by cellulitis, and an extremely serious condition may ensue.

The deflection of the great toe frequently affects the other toes harmfully, and gives rise to the hammer-toe which so often is associated with the second toe.

The head of the metatarsal is thickened by the repeated attacks of inflammation and the pressure of the boot. The cartilage is thinned. The sesamoids and tendons are displaced outwards. Exostoses often form about the condyles, and lipping occurs as in hallux rigidus.

Practically the boot is always to blame for the occurrence of this disease. It often begins in boyhood, and gives rise to no pain until later in life. Injury and diathesis, such as rheumatoid arthritis, may add to the severity of the affection.

TREATMENT.—In the early stages simple treatment will suffice. In this and in all stages suitable boots must be worn. The inner border should be straight, and the toe-piece squared. The inner border of the uppers of the boot should be sufficiently capacious to prevent pressure upon the toe-joint. Manual rectification of the deformity by exercises conducted while the patient's toe is properly directed, digitated socks, and perhaps a toe-post, are all useful. The toe-post may be introduced into the boot, or form part of the boot. In the latter event a vertical piece of stout leather is placed so as to lie in the space between the first and second toes, holding the first toe against abduction. At night a splint, reaching from the base of the metatarsal to the tip of the toe, with a large hole in the centre for the swollen bursa, and placed on the inner side of the foot, is often effective. Spring splints which can be worn in the boot are also used, but they are rarely comfortable. In more severe cases, where there are inflammation of the bunion and pain, a bar of leather or iron may be applied so as to traverse the sole of the boot, placed posteriorly to the metatarso-phalangeal range. This proves a great comfort, and allows the patient to walk without pain.

Operative Treatment.—In the earlier cases cuneiform osteotomy is sometimes performed. This can prove effective only when the prominent and sharp inner condyle is included in the wedge. Sometimes the removal of the sharp projecting bone will suffice. The operation which we recommend, however, as being in every way satisfactory, is excision of the metatarsal head. In this, care must be taken to remove enough bone to subsequently ensure good movement, or to cover the end of the bone with soft structure to ensure a movable joint. There is no occasion to exsect the sesamoids, which form an excellent protective pad for walking. Excision of the articulation, i.e., the head of the metatarsal and the base of the phalanx, is to be avoided, as the result is a stiff joint which interferes with walking. No operation should be performed while the bunion is inflamed. Rest and fomentations will usually cure the inflammation quickly. But if suppurative cellulitis has supervened, prompt incision should be made, and operation upon the bone postponed.

Robert Jones.

HAMMER-TOE.—This condition is usually associated with hallux valgus, and secondary to it, and consists of the contraction of one or more toes, usually the second. The second phalanx is flexed and the third extended. It is generally due to the crowding of toes by lateral pressure caused by ill-fitting shoes. In the early stages no complaint is made of the condition; but later, with the formation of callosities and sometimes ulceration, a very painful ailment exists, and locomotion is all but impossible. The condition is common both to childhood and to adolescence.

TREATMENT.—In the early stages this should consist in rectifying the hallux valgus and forcibly straightening the crooked toe. The surgeon should not be content until the toe be fixed in a splint in a hyperextended position, and so kept for fully a month. The toes should all be hyperextended on a metal splint applied to the soles, and flexed to an angle of 45° opposite the metatarso-phalangeal range. On to this splint the toes should be firmly bandaged. For many weeks the splint should be worn at night, and the patient shown how to hyperextend his toes manually.

In slightly more severe cases, tenotomy of the under portion of the capsule and division of the tendon may be necessary.

In pronounced hammer-toe, with shortening of all the structures on the plantar aspect, exsection of the joint may be needed, and it is a very successful operation. A circular incision is made round the callosity, the skin is exsected, and the joint opened. A V-shaped excision of bone is made, which should include the

joint. The skin wound is then stitched. The toe will then be straight and stiff, and will give no further trouble.

Amputation of the toe is never necessary, and no treatment should be undertaken unless the hallux valgus be treated also. Well-fitting shoes should be prescribed, allowing room for the free play of the toes.

Robert Jones.

HARE-LIP.—Hare-lip may be represented by every degree of deformity, from a slight notch on the red margin of the lip, to a complete cleft which extends as a fissure throughout the whole substance of the lip and involves the floor of the nostril. The cleft may be present on one or both sides of the prolabium, so that a single or double hare-lip is the result. In the extreme forms of double hare-lip, the premaxilla may have no attachment to the alveolar margin of the jaw, but remain elevated in front of the surface of the rest of the lip by its attachment to the anterior part of the nasal septum. With all varieties of hare-lip, one of the many forms of cleft palate may be associated. This association is only of importance from the point of view of treatment when the cleft in the palate is a complete one; that is, when the alveolar margin of the jaw is incomplete. The early closure of the defect in the lip appears to exert a beneficial strain upon the separated margins of the palate, and by approximating them, renders the gap in the palate narrower, and so more amenable to operative treatment later on. The only treatment of hare-lip is by operation. The main points for consideration are: (1) *The time when the operation should be performed*; (2) *The type of operation best suited for each variety of deformity*; and (3) *The after-treatment of the patient*.

Fig. 34.—Complete single hare-lip. The area to be removed is enclosed within dotted lines.

is treated, the better is the cosmetic result achieved in later years, advantage should be taken of the fact that very young infants can tolerate an operation on a hare-lip well, and it should be performed as soon as possible. Six weeks of age may be regarded generally as a favourable date, provided that the baby is a healthy one. Chronic nasopharyngeal catarrh and disorders of digestion are common minor ailments that must be rectified before operation is undertaken. The presence of a cleft palate does not require any modification of this rule, since access to the palate for a subsequent operation is not impeded by the previous closure of the lip. If the cleft of the palate is an incomplete one, the closure of the lip has no effect upon it, even though nearly all the hard palate may be involved in the deformity.

2. Type of Operation.—The aim of all operations upon hare-lip is to produce a lip with the closest resemblance to normal that is possible. Certain general details must therefore be rigidly attended to in all operations. Variations in the operations to carry out these details will be determined by the type of the deformity. The edges of the cleft must be pared so that the whole of the red margin lining the sides is cut away (Figs. 34, 35). If not done freely, a small island of red tissue is likely to remain incorporated in the white area of the

1. Time for Operation.—An operation for closure of hare-lip is a comparatively mild procedure, and is well borne by infants of only a few weeks old. Since it is a general surgical experience that the earlier in life a congenital deformity

restored lip, where it produces a very obvious disfigurement. These incisions must extend well up to the sides of the nostril if the hare-lip is a complete one. At the same time the attachment of the under aspect of the lip to the upper jaw must be cut away, and the tissues of the cheek freely undermined. These measures enable the two parts of the lip to be brought together without tension, and the two edges of the flattened nostril to be approximated so that its natural contour is restored. The first stitch should be inserted at the junction of the red and white portions of the lip on either side, and then tied so as to form a guide suture. The rest of the stitches can then be inserted on both aspects of the lip. Lane's finest curved cleft-palate needles, threaded with ophthalmic D. silkworm gut, are well adapted for the purpose, since the stitch-holes made by these subsequently become almost invisible. A wide mattress suture of the same material, embracing the tissues of the lip on either side of the junction, forms a useful accessory support.

The premaxilla will require special treatment when a complete cleft of the hard palate is associated with a hare-lip. If the cleft is unilateral, then the premaxilla must be gently broken at its attachment to the alveolar margin of the jaw, and moulded by pressure towards the opposite side until it fills up the gap. The opposed margins of the cleft are made raw by the removal of the superficial tissue, and a stout silkworm-gut stitch passed through the mucoperiosteum of the maxilla and of the premaxilla serves to hold these surfaces in contact.

If the complete cleft of the palate is a double one, so that the premaxilla is situated mesially and elevated in front of and above the cleft by its attachment to the nasal septum, the removal of a small wedge-shaped area of bone from its under aspect allows it to be pressed down gently into the gap and fixed there by means of stout stitches as described above. The soft tissue of the lip must then be freely detached on its under aspect from the premaxilla, and the edges pared (*Fig. 35*) in a similar manner to those of an incomplete double hare-lip.

Fig. 35.—Incomplete double hare-lip. The dotted lines indicate the area to be pared.

3. After-treatment.—A dressing should not be applied to the site of operation. It merely acts as a septic compress, and is likely to hinder the process of healing. The wound should be painted over with a solution of benzoin in ether, which can be renewed daily. This acts as an impermeable varnish, and is non-irritating to a baby's skin. Collodion is an irritant, and should not be used. The child can be breast-fed directly after operation whenever practicable. Crying can usually be prevented by skilful nursing. If this cannot be obtained, then mild opiates must be used, such as one-third-minim doses of tinct. opii, or small doses of bromide of potassium (gr. 5). There must be no hesitation in using these drugs, since crying is likely to put a strain upon the wound, with disastrous consequences. If the child shows any tendency to pick the wound, cardboard cuffs lined with wool must be applied to the elbow-joints to prevent the hands reaching the face. These are not resented by children, and are of extreme value in cases where the most skilled nursing cannot be obtained. The toilet of the nose must be attended to carefully.

George E. Waugh.

HAY FEVER (Vasomotor Rhinitis, Paroxysmal Rhinorrhœa).—For the purposes of treatment, hay fever, rose fever, paroxysmal rhinorrhœa, and vasomotor rhinitis may be regarded as the same affection. The treatment must be both general and local, and, when the cause is known, prophylactic treatment also may be carried out.

PROPHYLAXIS.—In genuine hay fever, when the patient suffers only during the hay season or the time of the flowering of grasses, the most satisfactory treatment, if the patient can afford the necessary time and money, is to send him away to a suitable place where he is removed from the noxious influences. If a patient who suffers annually from hay fever can spend the grass-flowering season in a place such as the Island of Heligoland, where there is no vegetation, or on the sea, he will escape his annual attack, and no other treatment will be required. Even residence at the seaside is often efficacious. In a similar way, if a patient suffers only when he is brought into contact with roses, peaches, cats, horses, or whatever the particular exciting cause may be, no further treatment is necessary if the cause can be determined and the patient can be conveniently removed from its influence. Very often, however, the patient cannot follow this advice, or it may be impossible to determine the exciting cause, and then other measures must be adopted.

GENERAL TREATMENT.—General treatment is important. The majority of patients who suffer from these affections are “highly-strung” or definitely neurotic individuals with a family history of similar neuroses. Others suffer only when the general health is below par, when they are overworked, run down, or depressed as the result of worry or of severe illness, and in many of these general treatment alone will effect a cure. In the first place any general disease or derangement of the health must be rectified. If suffering from general debility, the patient should be advised to rest, or to take a long holiday; he should be given a plentiful but light and nutritious diet, and, especially if thin, he may be recommended to take two or three pints of milk daily in addition to his ordinary food. In neurasthenic cases a modified form of Weir-Mitchell treatment may be necessary. In addition, certain drugs are often beneficial. Iron and strychnine always do good, and some patients derive decided benefit from a course of arsenic. (See NEURASTHENIA.)

LOCAL TREATMENT.—During the actual paroxysm immediate relief may be given by spraying the nose with cocaine. A 1 or 2 per cent solution may be used, and may be made more effective by the addition of epinephrin. These remedies, however, are extremely dangerous. The relief experienced is temporary, and is quickly followed by return of the symptoms in an aggravated form. More and more frequent recourse to the drug is required, until the patient may become its slave. This is especially apt to occur because the patients are almost invariably neurotic. Moreover, these remedies ultimately induce a relaxed condition of the nasal mucous membrane, and render the disease almost incurable by other treatment. Similar objections apply to the internal use of opium and belladonna, which also have been strongly recommended.

In genuine hay fever, pollantin may be tried. This is an antitoxin obtained from horses which have been injected with the toxins obtained from certain grasses. A few drops of this serum inserted into the eyes and nose will prevent, or at any rate diminish, the severity of the attacks in many people. As far as is known it has no deleterious effects. More recently, vaccine treatment has been tried, and has been found successful in some cases. Tests are first carried out to ascertain if the patient's hay fever symptoms can be excited by toxins derived from certain grasses, and if the test yields a positive result, the patient is immunized by repeated injections of these toxins. (See VACCINE THERAPY.)

In that form of hay fever generally known as paroxysmal rhinorrhœa, nasal

treatment should be carried out. In the first place any gross abnormality in the nose should be corrected. Spurs or deviations of the septum, polypus, hypertrophies of the inferior turbinates, adenoids, or other cause of nasal obstruction should be approximately dealt with. If no gross abnormality be found, the patient may be treated as for chronic rhinitis (see RHINITIS); a simple alkaline lotion should be prescribed, together with a soothing ointment, such as plain lanolin, or weak boric acid or menthol ointment.

If no gross abnormality be found, and simple measures have failed, the best treatment is the application of the galvano-cautery. This is a purely empirical treatment, but properly applied can do no harm, frequently does good, and sometimes will even effect a cure. In the first instance, I should recommend that the anterior ends of the inferior turbinates should be cauterized, two, or at most three, parallel lines being drawn horizontally along each turbinate. After one or two weeks the posterior ends of the turbinates should be similarly dealt with. If this fail, the cautery may be applied to the tubercle of the septum, that is, to an area on the septum opposite to the anterior end of the middle turbinate. This may be repeated on two or three occasions after intervals of at least a week. The cautery may also be applied high up and far back on the septum.

When the cautery fails and the patient suffers severely, further surgical measures may be adopted, provided the general condition is good. The best plan is to remove portions of the turbinates. The nose is packed with a solution of cocaine and suprarenal extract, and after twenty to thirty minutes a general anæsthetic is administered. In this way a good view of the interior of the nose is obtained and the operation is nearly bloodless. With cutting forceps, such as Mahu's or Grünwald's, a strip should be removed from the entire length of the inferior turbinates, enough being cut away to ensure a free passage through the nose even when the portion left is swollen. The middle turbinates, if œdematous or pressing against the septum, should also be dealt with, the anterior end or the whole of the turbinate being removed, as appears necessary. The greatly increased air-way through the nose resulting from this operation will effectually prevent the patient from suffering again from nasal obstruction, and the removal of much glandular and secreting tissue prevents the profuse watery discharge. In the most severe cases, where the nasal mucous membrane swells so much that the patient is unable to blow his nose, and suffers from severe headaches and constant dripping of watery discharge, the removal of the turbinates will relieve the worst symptoms, even when it fails to cure. Moreover, the removal of the turbinates in this affection never results later in the dryness of the throat and nose which may follow their removal in other conditions. *H. Lambert Lack.*

HEADACHE.—Headache may arise from many different causes. In treating it, therefore, we must endeavour to ascertain these causes and to obviate them. They will for the most part be found to group themselves under three heads:—(1) *Organic disease of the parts actually involved in the ache*; (2) *Irritation in other areas*: "*peripheral irritation*"; (3) *Morbid states of the blood*.

1. Organic Headache.—This is generally taken to mean headache resulting from organic disease of some part involved in the pain, i.e., the brain, the meninges, the cranium, or overlying structures. When resulting from organic disease in other parts of the head, such as the eyes, ears, nose, throat, or mouth, the headache is not generally spoken of as organic.

Syphilis is the most common cause of organic headache, and may affect not only the brain and its coverings, but also the cranium and overlying scalp, in which case there may be great tenderness. It is to be noted that syphilitic

headache may occur quite early after infection, even during the secondary rash; it is now known that the cerebral and spinal meninges may be affected as early as this. The pain is apt to be exaggerated at night, a feature which should always excite a suspicion of syphilis.

If there be the slightest suspicion that the headache is syphilitic, prompt and vigorous treatment must be adopted, for head pain frequently heralds a serious outbreak of cerebral syphilis, such as the blocking of a cerebral artery. The intravenous administration of salvarsan is the most effective remedy. Short of this the patient should be mercurialized and iodide of potassium given in not less than 1-dr. doses three or four times a day. This is no doubt a large dose, but even if iodism result, what is that compared with irretrievable damage of the brain?

Rheumatic or "nodular" headache has in recent years attracted a good deal of attention on the Continent, where it is regarded as quite a common form of headache. It occurs most frequently in middle-aged and elderly women, and is liable to be brought on by a chill, as by sitting in a draught after washing the hair. The pain is persistent and may last for years. It is apt to increase at night and to be aggravated by the recumbent posture. Cold applications tend to increase, warm applications to relieve it. Careful palpation discloses within the subcutaneous tissues of the scalp and neck, in the substance of the cervical, occipital, and temporal muscles, or along the tendinous insertions into the occiput of the cervico-occipital muscles, circumscribed indurations highly tender to the touch. These consist of nodules varying in size from a millet seed to a bean. Along the tendinous insertions of the occipital muscles they usually form flattened masses. The nodules within the muscles are most easily felt when the latter are relaxed. The tenderness of the masses is due to the presence within them of sensory fibres (e.g., from the fifth, and the large and small occipital nerves), and the headache is sympathetically induced, just as it may be from other forms of peripheral irritation (e.g., disease of the teeth).

The treatment of this form of headache is general and local. As regards the former, the digestive system should be carefully attended to. The patient should abstain from alcohol. The hair should not be washed in water, but spirituous lotions used instead, and care should be taken to avoid chills. Among drugs, pot. iod., sod. salicyl., and pot. brom. are the best. Local treatment is *all-important*. It consists of massage of the head and neck, preceded by a two hours' application of hot poultices. Each manipulation lasts from fifteen to twenty-five minutes, and the entire course from one to three months. The first eight to ten manipulations generally cause considerable pain, and increase the headache, so that it may be necessary at this time to give anodynes, such as codeine and phenazone. Improvement begins from the third to the sixth week. The manipulations should be carried out every day until decided improvement occurs, when they should be limited to alternate days, and persevered in until all the indurations have been resolved. The necessary skill in manipulation can only be acquired after some practice. The patient assumes the sitting posture, resting his chin on both hands so as to steady the head. The operator begins by making downward strokes with the palms of the hands along the sides and back of the neck (effleurage); the underlying muscles are then vigorously kneaded, the deep ones being as far as possible plucked up from their supports (pétrissage). The indurations—subcutaneous, intramuscular, and intra-tendinous—are then individually kneaded, for about half a minute, by three or four finger tips, closely approximated, the movement adopted being a circular one from the shoulder-joint. Then follows a repetition of the effleurage. The same routine is gone through in the case of the scalp, and the sitting is terminated by a general effleurage of the entire head.

In headache from non-syphilitic tumour, opium still remains our sheet-anchor. In some cases of organic headache, as in abscess, tumour, or increased intracranial tension from whatever cause arising, relief may be afforded by trephining the skull (decompression). Sir Victor Horsley has by this means cured also traumatic headaches of many years' duration. When the root of the fifth nerve is involved, causing trigeminal neuralgia, the main branches of the nerve may be injected with a 70 per cent solution of alcohol (80 drops); or the Gasserian ganglion itself may be injected through the foramen ovale. Lumbar puncture is sometimes helpful.

2. Headache from Peripheral Irritation.—In all these cases, every possible source of the irritation must be sought for.

The scalp should be first examined. Among the poor, pediculi capitis are a frequent cause of distressing headache, and it should be remembered that in women the hair in the occipital region may conceal numerous pediculi and nits, even though on superficial examination the head may appear to be quite clean. The mere weight of the hair, by tugging on the scalp, may cause headache, as may also binding it up tightly, the wearing of a heavy headdress, or a hard-rimmed hat which compresses the scalp. Fortunately, very light silk hats and "bowlers" are now on the market for men, and are greatly to be preferred to the heavier kinds, being not only less productive of headache, but also less likely to cause baldness by strangulating the vessels of the scalp.

Irritation in the region of the eyes, such as may be caused by eyestrain, or by looking at bright lights, vivid colours, or rapidly-moving objects, is a frequent and potent cause of headache. The greatest care must be taken to obviate eyestrain if present, by correcting errors of refraction, fixation, and the like. Nor must it be forgotten that glaucoma, both in the acute and chronic form, is a possible cause of headache.

Disease in the nasal passages and accessory sinuses—frontal, maxillary, ethmoidal, and sphenoidal—as well as in the nasopharynx, may cause headache. Adenoid disease is another not infrequent cause. Certain perfumes also, as those of the lily and hyacinth, may induce it. Again, affections of the pharynx and tonsils, e.g., acute pharyngitis and tonsillitis, cause headache, chiefly in the parietal and occipital regions.

The auditory apparatus may be the starting-point of the pain. Loud noise may induce it, as may also otitis media, the presence in the meatus of a mass of hardened cerumen, and indeed almost any affection of the ear. The pain may be a mere earache, or it may spread to the whole of the same side of the head, and even involve both sides.

Among the dental causes of headache must be reckoned difficulty of eruption, either of the temporary or the permanent teeth, overcrowding, caries, exostoses, buried fangs, peri-odontitis, unsuitable fillings, or imperfectly fitting plates. Let it not be forgotten that the tooth which is responsible for the headache may itself be perfectly painless. If any dental trouble exists, the services of the dentist will sooner or later be required, but in the meantime the medical man may afford temporary help. In difficult eruption, lancing the gums may relieve. In acute peri-odontitis, the overlying gum should be counter-irritated, and 2 gr. of sulphide of calcium, or 5 gr. pil. saponis co. (B.P.), or 3 to 5 gr. of calomel, may be given. In applying anodynes to a carious cavity, the latter should first be syringed with tepid water, and then thoroughly dried with pellets of cotton-wool. Some recommend the removal, with the help of a mouthglass and a few excavators, of the soft dentine, an operation which may be safely undertaken by the practitioner himself. After the anodyne has been applied, the cavity may be packed with wool partially moistened with mastic, care being taken not to press too firmly in the direction of the nerve.

One of the following applications may be used :—

R	Acidi Carbolici (sat. sol.)		R	Liquoris Opii Sedativi	
	Chloralis Hydratis (sat. sol.)			Olei Caryophylli	āā 3ij
	Tincturæ Opii Camphoratæ	āā 3j		Camphoræ	3iss
	Olei Menthæ Piperitæ	3ss			

With regard to reflex headache from affections of the thoracic and abdominal viscera, Head has pointed out that these may not only cause reflected pain and tenderness in the correlated areas of the body wall, but also, if sufficiently intense, headache and scalp tenderness. Broadly speaking, the relation between the scalp and trunk areas is such that the higher the area in the trunk, the further forward is the correlated area in the scalp ; thus the third and fourth cervical and upper thoracic areas are associated with areas over the nose and forehead : the seventh, eighth, and ninth thoracic with areas in the temporal, vertical, and parietal regions ; and the tenth thoracic with the occipital region.

So far as disorders of the digestive viscera are concerned, headaches secondary to them are in the main due to secondary implication of the blood, and therefore come under *Class 3*.

The same is true of headaches associated with disturbance in the reproductive system. It is probably only exceptionally that such headaches are reflexly induced. Those associated with menstrual irregularities are certainly of hæmic origin.

3. Headaches due to Morbid States of the Blood.—These are, of all causes, much the most common ; indeed, functional headache seldom, if ever, occurs when the blood is healthy. Therefore, in such headaches always suspect the blood, even though marked peripheral irritation be present ; and should it be unhealthy, seek to make it healthy and to raise the patient's health to the highest possible level. Measures to this end are eminently rational, in that they strike at the root of the evil ; anodynes, though they may alleviate for the time, do but mask the trouble.

Among the blood conditions productive of headache are the following :—

Plethora, such as one meets in the overfed, and in stout amenorrhœic women at the climacteric. This condition should be treated by limiting the diet, by giving mercurials and salines, and in severe cases by bleeding. Attention may here be drawn to the fact that passive congestion of the head, and the consequent headache, are favoured by wearing stiff tight collars and tight corsets.

High Arterial Pressure, whether of the renal variety or not. In these cases the heightened pressure indicates some faulty blood state which it should be our business to correct. Otherwise the treatment is the same as for plethora. In severe cases rest in bed and complete or partial starvation are indicated.

Low Arterial Pressure. This may be a feature of intractable headache, and in some of these cases digitalis is of service.

Anæmia, in any of its many forms. Headache thus resulting is apt to be neuralgic.

Indigestion Toxæmia (by which I mean blood-poisoning from defective digestion in stomach, bowel, or liver), including as it does the toxæmia of gout, "biliousness," and constipation, is of all causes of headache the most common. Obscure forms of intestinal and hepatic indigestion are especially apt to cause it, and it is probable that megrim, and not infrequently also the headaches associated with menstrual disturbances, arise in this way.

The importance of paying attention to the digestive system, in all sufferers from headache, cannot indeed be exaggerated. Their diet must be regulated with great care. Some patients require feeding up ; others, especially those past middle life, may need to have their diet restricted. For most, the golden

rule should be to eat simple food, in moderate quantity, and to chew it well, especially the farinaceous portion of it.

In some headaches, more especially megrim and its allies, benefit may be obtained by diminishing the quantity of animal food. A mere curtailment in the amount of butcher's meat may suffice; or it may be necessary to forbid it altogether; or, again, to prohibit bird, or even fish, limiting the diet to vegetable food, dairy produce, and eggs. Sometimes help may be got by putting the patient on a so-called "purin-free diet." The purins include uric acid, xanthin, hypoxanthin, theine, caffeine, and theobromine. They are to some extent formed within the body, but chiefly taken in with foods. Meat, meat extracts, liver, thymus, pancreas, and kidneys contain them in abundance; also many cereals, some fruits (e.g., strawberries), peas, beans, lentils, spinach, asparagus, onions, mushrooms, malt liquors, tea, coffee, and cocoa. The following are among the more important purin-free foods: nuts, chestnuts, dates, white bread, macaroni, potatoes, milk, cheese, butter, eggs, apples, grapes, raisins, figs, and honey.

It is a fact, however, that these headaches can also be benefited, and even cured, by an entirely opposite plan of treatment, i.e., by curtailing, or actually withholding, carbonaceous foods, as in the Salisbury treatment. Dr. Francis Hare claims to have obtained better results in megrim and the paroxysmal neuroses generally by treatment on these lines than on the opposite plan. Such has been my experience also. We must not, therefore, bind ourselves to any one system of diet in the treatment of headache, but consider each case on its own merits, and if we find that one plan does not answer, try another, our object being to secure normal digestion in stomach, bowel, and liver. If we succeed in this, it probably matters little what kind of food we give; for with normal digestion, the blood poured by the hepatic veins into the systemic stream will be healthy—uncontaminated by the products of defective digestion—and thus adapted to normal nutrition.

In treating periodic headaches and allied conditions by reducing the carbonaceous intake, Francis Hare usually begins "by placing the patient on a small, mainly proteid diet, consisting of, say, 8 to 12 oz. of cooked lean meat or fish, with $1\frac{1}{2}$ oz. of bread or toast and a little butter; green non-starchy vegetables are admissible, also tea and coffee, with a little milk but no sugar. The enforcement of such a daily diet, except in those who are extremely emaciated, is almost of necessity accompanied by a daily loss of weight. This loss is carefully estimated by weighing every day or on alternate days; this gives some index of the addition of the carbonaceous supply which is required. By carefully adding to the amount of carbohydrates and fats, preferably by very cautiously increasing the allowance of bread-foods, butter, and milk, we arrive shortly at a diet under which the body weight remains stationary. Carbon equilibrium is then being maintained with the *minimum carbonaceous intake*."

It should be noted that headaches which have resisted every other form of treatment can often be cured by change of air and scene; and it is probable that in such cases the good is effected essentially through the digestive system; digestion is improved, and this leads to a better quality of blood and to improved nutrition generally. One may see a nervous, jaded, headachy woman, whom in her own home no kind of treatment benefits, return, after a few weeks congenial holiday, full of the joy of life and without ache or pain of any kind.

The Toxæmia of Fever.—Febrile headache is apt to be accompanied by painful throbbing. Cold applications to the head relieve the pain.

Uræmia.—Headache, especially in the occipital region, is one of the classical signs of this condition. It may occur some time—in the case of granular kidney, many years—before the onset of the acute stage. Headache which appears for the first time, or gets worse, after middle life, should always arouse suspicion of

granular kidney. Headache arising in this way may take the form of classical migraine. Calomel should be given by the mouth at night—short of touching the gums. It is a mistake to suppose that patients with granular kidney are intolerant of mercury.

Alcohol, Tobacco, and Drug Toxicæmia.—The headache which follows upon a drunken debauch is well known. It is hardly necessary to observe that immature wines and spirits are much more likely to cause headache than the more mature varieties, nor to dwell upon the idiosyncrasies which are met with in respect of special alcoholic drinks—how, e.g., some cannot drink even a moderate quantity of good champagne without suffering from headache the next day, while others can tolerate champagne and not burgundy, and so forth. In general, it may be said that those prone to headache are best without any alcohol whatever.

Though smoking cannot be said to be a frequent cause of headache, it is a possible one.

In reference to drug headaches, it is important to remember that drugs, like iron and quinine, which have been wont to cause headache, can often be tolerated if they are given in small doses at first and then cautiously increased. Nor must it be forgotten that imagination may play a considerable part in the production of these headaches, and when this appears to be likely, it is well to keep the patient in the dark as to the drugs he is taking.

A few causes of headache not falling under any of the above headings still remain for consideration.

Mental Causes.—Intellectual effort may be a cause, as in the case of Newton, who is said always to have suffered pain in the head while working at the theory of lunar irregularities. This is, however, a much less frequent cause than emotional disturbance. School headaches result rather from eyestrain and from the emotional excitement attendant upon over-pressure, than from actual intellectual effort. Violent emotions, such as anger, may set up headache, and worry and suspense are yet more productive of it. Sufferers from headache should, as far as possible, live a serene and unemotional life.

Exertion.—Muscular exertion, especially if violent, or if pushed to the point of fatigue, or if necessitating stooping, as in gardening, may start a headache. Exercise within proper limits, however, may ward off headache.

Atmospheric Conditions.—Excessive heat and cold, and low barometric pressure, may all induce headache. Indeed, persons liable to headache are very susceptible to these and the other subtle influences which go to make up climate: thus, a person may be a martyr to headache in one place and entirely free from it in another, a fact to be borne in mind in recommending change of climate. As a rule, moderately bracing climates are the best, and inland resorts better than seaside.

Hot, stuffy rooms are highly provocative of headache. Those prone to this affection stand in pressing need of fresh air by day and by night.

Topical Treatment.—*Cold*, applied to the head by means of damp cloths or the ice-bag, is useful in headaches attended by throbbing, such as may occur in fever and migraine. In the latter affection it often happens that the head is flushed and throbbing while the rest of the body is unpleasantly cold. In these cases steps should be taken to make the body and the extremities warm, e.g., by warm wraps, and by putting the feet in hot mustard and water, or even by immersing the entire body in a hot bath, while cold is applied to the head.

When there is difficulty, as during delirium or sleep, in keeping the ice-bag constantly applied to the head, the patient may use as a pillow an indiarubber bottle or water-cushion filled with crushed ice and covered with the sheet.

In other cases, as in "rheumatic" headache, the opposite plan of applying

Heat to the head is beneficial, e.g., by means of a calico sand-bag heated to 120° F. and applied for half an hour three or four times a day. Good may also be got from the application of heat or cold to the neck.

The *Seton* is useful in obstinate forms of chronic headache, especially migraine. A portion of skin at the back of the neck is transfixed with a scalpel, and a probe passed through the wound; the knife having been withdrawn, a piece of ordinary household tape, about nine inches in length, is tied to the probe and pulled through the wound, and the ends are then loosely tied together. The patient is instructed to move the tape from side to side every day. The seton should be worn for three months at least, and if the pain recurs, a second, or even a third should be applied. Dr. F. Hare considers that the seton benefits by inducing a mild febrile state, thus promoting the oxidation of substances, the presence of which in excess may induce paroxysmal neuroses, headache among others. (See SETON, TREATMENT BY.)

Blistering may be of service, but it is apt to leave an unsightly scar. Croton-oil liniment (B.P.), if well rubbed in, is equally efficacious, producing a copious crop of pustules which leave no scar.

Dry Cupping is sometimes helpful. Half a dozen cups should be applied just below the clavicles and between the scapulæ, and smaller ones in the region of the ears, a procedure which may be repeated frequently.

Among *Anodyne Applications*, the following may be employed:—(1) Liniment. opii (B.P.); (2) Liniment. belladon. (B.P.); (3) A drachm each of chloral, camphor, and chloroform, with half a drachm of morphia, to be brushed in for its anæsthetic effect; (4) Twenty drops each of oil of cloves and oil of cinnamon, with one drachm of menthol and an ounce of alcohol; (5) One ounce of tinct. belladon. and ten drops each of tinct. aconit. and tinct. chloroform.; (6) One part each of chloral and menthol, two parts of cocoanut butter, and four parts of spermaceti; (7) Half a grain of croton oil, with two ounces of petroleum ointment.

Electricity, either in the form of faradism, galvanism, the high-frequency current, or franklinism, may be useful. In employing galvanism, the negative pole should be placed on the nape of the neck and the positive moved slowly over the forehead, with an occasional reversal of the current; if faradism is used, the current should be mild, and applied to the temples or the cervical sympathetic, or recourse may be had to the wire brush.

Massage of the head and neck is often of service, especially in rheumatic headache, as already pointed out.

Bleeding is indicated in the headache associated with plethora and high arterial tension, above all in that of acute uræmia. Its beneficial influence on headache is well shown in the case of spontaneous hæmorrhages, e.g., from the nose, rectum, or uterus.

Firm Pressure to the head, such as is afforded by a closely fitting capeline bandage, often relieves headache, especially headache attended by fits of throbbing. Sarason has constructed an apparatus (made by Schönlein & Co., Munich) which he calls a megrainator. It consists of two pads which can be pressed firmly against the temples by an adjustable spring. He has found it useful in many cases of megrim.

Compression of the Temporal Arteries is sometimes of service. For this purpose it has been recommended to employ a semicircular band of steel, provided at each end with a movable pad, so that the pressure need not always be applied to exactly the same spot.

Trephining, as already stated, may be called for in organic headache.

Lumbar puncture may be helpful in reducing intracranial tension.

Drug Treatment.—Of the various anodyne drugs employed in the treatment

of headache, the best are antipyrin, phenacetin, acetanilide, acetyl-salicylic acid, citrated caffeine, and opium; but it should ever be remembered that such drugs do little more than relieve the pain for the time being, leaving the root of the evil untouched.

In syphilitic headache, iodide of potassium should, as before observed, be given in heroic doses, e.g., 1 dr. three or four times a day, either alone or combined with small doses of mercury.

In violent neuralgic headache, we may prescribe $\frac{1}{2}$ -dr. doses of ammonium chloride, combined with $7\frac{1}{2}$ drops tinct. gelsemii and a drachm of syrup. aurantii, the mixture to be repeated every hour until three doses have been taken. Butyl chloral hydrate, in 5-gr. doses, is also useful in neuralgic headache and in the headache of anæmic girls. It readily dissolves in glycerin, or it may be suspended in mistura amygdalæ (B.P.) with a drachm of syrup.

The inhalation of 10 to 20 drops of chloroform, either from the hand or from a piece of lint in a wineglass, may be of service, as may also the simple and saline ethers, e.g., $\frac{1}{2}$ to $1\frac{1}{2}$ dr. of the simple or compound spirits of ether, or the same quantity of spiritus ætheris nitrosi. Oxygen inhalations are often of great service.

Nitrite of amyl and nitroglycerin may be tried when the arterial blood-pressure is unduly high. The latter drug, given for weeks together, is said to be useful in averting the attacks of migraine, for which also guarana is sometimes helpful, one to two drachms of the powder being given in hot water sweetened with sugar, or the fluid extract may be prescribed in drachm doses. Turpentine, in 10 to 20-drop doses, sometimes does good; it should be mixed with mucilage, and flavoured with oil of cinnamon, in 1-drop doses.

Quinine, in 10-gr. doses, is indicated in malarial headache, or in any severe periodic headache, e.g., one coming on at the same time every day or night; it should be given just before the expected attack.

In some of the slighter forms of headache, acid mixtures are useful, e.g., 10 drops of dilute nitrohydrochloric acid, 25 drops tincture of nux vomica, $\frac{1}{2}$ dr. each of tinct. gent. co. and syrup. aurantii, made up to an ounce of water.

Lactate of calcium or chloride of calcium, in 5 to 15-gr. doses thrice daily, may be of service when the coagulability of the blood is subnormal. They may be prescribed as follows:—

R Lactate of Calcium	gr xv	Chloroform Water	3j
Tincture of Capsicum	$\mathfrak{m}\frac{1}{2}$		
(Or, 15 grains of the lactate may be dissolved in a third of a tumbler of water.)			
R Chloride of Calcium	gr xv	Camphor Water	3j

This treatment should be continued for at least three weeks. (See also MIGRAINE.)

HEAD-NODDING.—(See NYSTAGMUS.)

Harry Campbell.

HEALTH RESORTS.—These are most conveniently divided into (1) Climatic stations, and (2) Spas. The first group includes those resorts which are esteemed chiefly on account of their possession of some special climatic virtue, such as high altitude, desert air, or sea air; the second comprises stations which rest their therapeutic claims mainly upon the possession of natural mineral waters, used either internally for drinking, or externally for bathing.

1. **Climatic Stations** fall into classes according to their effects upon general metabolism, of which, in a general survey such as this article offers, it is possible to consider only the two extremes. A bracing climate is one which promotes metabolism and leads to the expenditure of vital force. A relaxing or sedative climate acts inversely; it retards metabolism and hinders the vital powers.

Expressed in terms of ordinary drug remedies, the one might be compared to ammoniated quinine, the other to bromide of potassium. Differences in the effects produced by the two kinds of climate are due in the main to differences in the degrees of humidity in the atmosphere. Dry climates are bracing; humid climates are sedative or relaxing. Dry climates are subject to sudden and considerable variations of temperature, and call forth, in consequence, very brisk reactions in those who are subjected thereto. The all too common prescription of "some good, bracing climate" for the debilitated convalescent is very much to be deprecated; for such climates frequently make demands upon the physiological resources of invalids with which the latter are unable to comply. Humid climates are not open to this objection. Their characteristic is equability of temperature. The aqueous vapour in the air acts the part of a poultice, and prevents that rapid radiation of heat from the earth which in a dry atmosphere is inevitable. Such climates are disagreeable to most healthy people, who find themselves thereby rendered lethargic and somnolent; but for invalids, the very old, and the delicate young, they are eminently suitable. It should be observed that the humidity of the air in a locality has no ascertainable relation to the rainfall. There are many places whose humidity is high which nevertheless have a low rainfall, and vice versa. Humidity is usually expressed in percentages of saturation. Saturation of the atmosphere with aqueous vapour being taken as 100, a high relative humidity would be anything approaching 90, a low relative humidity would be anything below 60. Low humidity characterizes the stations on the east coast of England, notably in the Isle of Thanet (Westgate and Margate), and this coast supplies in consequence our most bracing climates. The further south and west we travel, the greater becomes the humidity and the more sedative the climate; until, on the southern coasts of Devonshire and Cornwall, we arrive at stations such as Sidmouth, Torquay, and Falmouth, which may be considered as typical examples of the sedative class.

The character of an inland station may be gauged to some extent by its situation and exposure. Low-lying, sheltered places tend to be relaxing; those which are well elevated above sea-level, especially if they be fully exposed to the sun and the prevailing winds, are for the most part bracing. A moderate elevation may be taken as 1000 feet. Below this figure a station inclines to be sedative; anything above this figure may be regarded as bracing, and when 2000 feet is reached we arrive at what is known as moorland or sub-mountainous climates, which are emphatically bracing. The most characteristic type of bracing climate is supplied by those stations which are called stations of altitude. These are chiefly to be found in Switzerland, and the best known among them are Davos (5000 ft.), Arosa (5500 ft.), St. Moritz (5800 ft.), and Leysin (4700 ft.).

A favourite centre for trying various degrees of altitude is Montreux, on the Lake of Geneva. Easily accessible from this centre are Les Planches (1400 ft.), Glion (2250 ft.), Caux (3600 ft.), Les Avants (3500 ft.) and Rochers-de-Naye (6470 ft.), all of which, except the last-named, are winter as well as summer resorts. They all have excellent accommodation.

Such climates as these places present are most unsuited to people who suffer from real organic disease as distinct from mere disturbance of function. This is pre-eminently true of renal disease, heart disease, emphysema, and of any condition where the aeration of the blood is difficult or deficient. All cases which show a high blood-pressure should be very especially cautioned against high altitudes. The proper utilization of such climates in tuberculosis is a very complex matter, into the details of which it is impossible to enter here. It may, however, be laid down as a general rule that only those cases which give hope of brisk and considerable recuperative power should be subjected to the trying

conditions which high altitudes necessarily entail; and it is well to remember that in this disease climatic considerations are as nothing compared with the minutest observance of open-air principles.

The choice of a climate for an individual case is never an easy matter. Invalids are exacting and weather is capricious, so that however excellent our choice may be in theory, it not infrequently proves unsuccessful in practice. Such want of success is always disappointing, but we may save ourselves from the humiliating consideration of having done actual harm if we are careful to observe certain well-defined rules. They consist in an estimate of the patient's powers of response to metabolic stimuli, and the application of the above-mentioned general divisions of climates. It is a very common mistake for the prescriber to select for his patient the type of climate which he has found most suited to his own case. As most prescribers prefer a bracing climate to a sedative, and as it is necessarily a few only who have any personal acquaintance with foreign stations, the aged and the organically unsound are not infrequently hurried to distant countries, to their undoing. It is necessary to repeat, then, that really bracing climates are suited only to those who have ample recuperative power, and should never be prescribed for such as demand that their vital powers should be husbanded. Especially does this apply to the subjects of cardiovascular disease, renal disease, and disease of the central nervous system. For such patients, and for those suffering from emphysema and other decreescent disabilities, the sedative climates of our west and south-west coasts are eminently suited. Abroad, Pau and Arcachon may be mentioned as sedative winter stations to which such patients may be recommended with confidence: Biarritz, though more bracing than either, may be regarded as well within the sedative category.

The climate of the Riviera is *sui generis*. Most of the stations, especially Mentone and San Remo, inasmuch as their humidity is relatively high, are of the sedative order, but they are nevertheless subject to very rapid and decided changes of daily temperature. It is warm and relaxing during the day, but at sundown it suddenly becomes cold and bracing. The amount of sunshine, and the excellent accommodation to be obtained at most of the stations from Cannes to San Remo, have made the coast justly popular with English people, but it is frequented as a playground rather than as a sanatorium.

The climate of Egypt is also *sui generis* in that it combines a very low relative humidity with a remarkable equability of temperature. Both these characteristics are becoming very much less marked since the vast scheme of irrigation from the Nile has been producing its effect upon the country. Cairo, from its insanitary state, is not at all suited to invalids, but Helouan, fifteen miles to the south, is an excellent health resort, with warm sulphur waters and a good bathing establishment. Algiers presents a climate midway between those of the western Riviera and of Egypt. The stations there, Hammam R'Hira, Hammam Meskoutine, and Biskra, are all agreeable places in which to winter. The cost of living is rather less than in Egypt.

2. **Spas.**—Health resorts which have natural mineral waters are commonly known as spas. Attempts have been made to classify such stations according to the chemical composition of their waters. It is, however, becoming increasingly evident that such therapeutic powers as these waters possess depend less upon their exact chemical ingredients than upon some physico-chemical activity such as radio-activity, the exact nature of which remains to be demonstrated. Moreover, certain spas have, so to speak, specialized in certain classes of complaints, and such specialization has in many cases evidently not been dictated by anything in the chemical composition of the waters. It is therefore not only less confusing, but, in the present state of our knowledge,

much more rational, to classify spas not upon a chemical scale but upon their therapeutic indications. Before attempting such a classification, it must be premised that spas are not exempt from climatic influences, so that in choosing a spa the physician must not lose sight of the general principles of climatology which have already been indicated.

Spa treatment is suited only to the earlier stages of chronic disease ; in no circumstances should acute cases, or those which are far advanced, be advised to undertake the fatigue of long journeys, the expense, the anxiety, the unfamiliarity with surroundings and perchance language, which such treatment of necessity entails. Some of these factors contribute very powerfully to the beneficial effects produced in suitable cases, the element of change being of the essence of the "cure" ; but in acute or advanced cases they are altogether harmful.

Spa treatment is thus pre-eminently the treatment of chronic disease. Most chronic disorders may be brought under three heads : gouty, syphilitic, and tuberculous. The last-named may for obvious reasons be dismissed ; the second will be considered later ; there remains therefore the question of gout, the commonest and most potent cause of chronic affections.

GOUT.—Almost all spas undertake to treat gout, or rather the gouty state ; for gout in its acute form offers no exception to what has just been stated. The gouty state may express itself clinically in many different ways. The gouty patient may complain of gastro-intestinal troubles, he may be the subject of respiratory disorders, his circulatory system may be affected, he may be troubled in his joints, or suffer from cutaneous eruptions. One gouty person may be irritable, another melancholic ; some are plethoric, others anæmic. In the case of a disease of such protean aspects, it is not surprising that a great variety of spas should undertake the management of its victims, and perform it with considerable success. For the fact is, the successful treatment of the gouty state depends upon general hygienic considerations—diet, exercise, and activity of all the emunctories—which can be imposed at one spa almost as readily as at another, so that the choice in an individual case, though it should depend upon the indication afforded by the most troublesome manifestation, may within certain limits be decided by questions of predilection and convenience.

It is impossible here to attempt anything like an exhaustive analysis of the stations which have specialized in particular branches of goutiness, but a few instances may be serviceable. In the chronic or subacute arthritic manifestations of the gouty state, Aix-les-Bains, in Savoy, takes the first place. It has a world-wide reputation, and the physicians are very experienced in all matters pertaining to disorders of the joints. In this country, Bath in winter, and Buxton and Harrogate in summer, may be recommended with confidence in the same and similar conditions. In gastro-intestinal disorders, Carlsbad, Marienbad, Vichy, and Brides-les-Bains are the best known. The first two are suited more especially to the strong and plethoric ; the last two in the case of the weakly and debilitated. Certain other stations, such as Homburg, Kissingen, and Wiesbaden, have attained to a reputation in the gastro-intestinal disorders of the gouty. Inasmuch, however, as they all contain a considerable amount of common salt in their waters, they cannot be regarded as altogether free from objection. Chloride of sodium is very unsuitable to most gouty people.

Respiratory Disorders are much more frequently caused by an underlying gouty state than most people imagine. This is particularly true in the case of children of gouty parentage, in whom nasal, pharyngeal, and bronchial troubles are very liable to occur, and in whom the orthodox treatment is often very disappointing. Asthma, and chronic bronchitis with occasional acute ebullitions, in adults, should always raise a suspicion of the responsibility of

goutiness for the attacks. The three principal stations which have specialized in these conditions are Mont Dore, Ems, and Caunterets. Mont Dore is situated in the centre of France (Puy-de-Dôme), at an elevation of 3500 ft. The waters contain a small quantity of arsenic, which is erroneously supposed to confer upon them their special qualities. The "cure" is conspicuously beneficial in cases of asthma—more especially bronchial asthma—and chronic bronchitis. Pure nervous asthma and other functional nervous disorders also derive benefit. Ems is a much more sedative station than Mont Dore. Its elevation is but 260 feet, but it is very beautifully situated among wooded slopes on both banks of a small river. The only objection to it is that it is apt to be unduly hot in July and August. Caunterets is situated at an elevation of 3200 feet in the Pyrenees, and is a very popular resort for all respiratory disorders, more especially for those which affect the larynx. It is invaded during the season by actors, orators, singers, and others who use their voices much.

Circulatory Disorders are not of course a special appanage of the gouty state, though they are so to a greater extent than is commonly supposed. The French have a saying that gout is to the arteries what rheumatism is to the heart; and a timely recollection of this association would often lead to a prevention of arterial disease. By ridding the system of the poisons whose gradual accumulation leads to such disease, spa treatment may effect a great deal; but the appeal which is made in such circumstances is a general one for increased metabolic and excretory activity rather than one which is directly addressed to the vascular system. There is, however, one exception to this generalization which deserves more than a passing notice. One of the most troublesome forms in which the gouty state is liable to show itself is an inflammatory disturbance of the veins, especially of the lower extremities, which is particularly rebellious to ordinary treatment and very liable to recurrence. There is a station called Bagnoles-de-l'Orme, in Normandy, which in such conditions is capable of producing effects which approach the miraculous. It is unfortunately very little known in this country, but its accessibility and its admirable equipment, no less than its agreeable climate, render it well worthy of the attention of English physicians.

With circulatory disorders which originate in the heart itself the reputation of Nauheim had at one time become so intimately associated, in the minds both of the profession and the public, that a dispassionate estimate of the claims of this spa could scarcely obtain a hearing. Unquestioning belief in the exaggerated statements of astute advertisements may last long enough to afford a commercial justification for such methods, but scientific truth is invariably vindicated in the long run, and most medical men now realize that there is nothing magical in the Nauheim waters, that the methods as practised at this spa are equally well administered elsewhere, that these methods, so far from affording a sovereign remedy in all cardiac cases, are in reality of very limited application, and, finally, that Nauheim itself is not only inaccessible from this country, but that its climate leaves a great deal to be desired. The places at home at which effervescing baths and resistant exercises can be obtained include London, Bath, Buxton, Harrogate, Sidmouth, and Llangammarch Wells. The last-named, by a scientific use of its barium waters, has attained results which are in many cases superior to those which may be expected of the Nauheim methods.

In France there are two stations which have specialized in cardiac disorders, namely, Royat and Bourbon-Lancy. Both these spas are in the Puy-de-Dôme district, not far from Mont Dore, both are pleasantly situated, and both are admirably equipped for the treatment of those cases which they seek to attract. Royat was originally, and to a large extent still remains, a spa at which the treatment of all the manifestations of the gouty state was undertaken, but the

impetus which recent investigations have given to the study of cardiovascular disorders, together with its possession of carbo-gaseous waters, has caused it during the last ten or fifteen years to specialize in the treatment of the cardiopathies of the gouty state. Hence it is that functional cardiac troubles and the numerous cases in which the central organ is bending under the burden of increased peripheral resistance, no less than those in which vascular tone is deficient, find at Royat a degree of amelioration which is scarcely to be found elsewhere. Bourbon-Lancy is to heart affections of rheumatic origin what Royat is to those of gouty origin. It is not that any pretence is there made that valvular lesions can be cured, but the two claims that are put forward are usually amply justified by results in well-selected cases. These claims are, first, that a course of treatment there tends to eradicate the rheumatic habit, and thus guards against a recurrence of endocarditis; and secondly, that in recent cases, more especially in young people, the functional capacity of the heart is educated to overcome its mechanical disabilities. There are very few spas which fulfil their claims so satisfactorily as Bourbon-Lancy.

The *Cutaneous Affections* in which benefit may be expected from spa treatment are those in which the dermatosis is of general rather than local origin, and the treatment resolves itself consequently into that of the underlying cause. Many of the sulphur-water spas make a special point of the treatment of cutaneous affections, especially of such as are associated with the gouty state. In this country, Harrogate and Strathpeffer enjoy a well-deserved reputation; in France, Luchon in the Pyrenees and Uriage in the Alps are very agreeable and much patronized stations. Mention ought also to be made of St. Christau, a spa which has the unusual merit of being open in winter as well as summer. Its waters contain a salt which is a very uncommon constituent in natural mineral waters, namely, sulphate of copper. St. Christau is in the Pyrenees, close to Pau. It is a very agreeable and well-regulated little spa, which deserves to be better known.

So far we have considered chiefly the gouty states which show themselves by some such obtrusive manifestation as arthritis, hepatic congestion, vascular disturbance, or what not. There are, however, cases of goutiness which present no such salient features. These occur in people who, though they may present a large number of the stigmata of the diathesis, have nevertheless no symptom which marks them as more suited to one spa than another. Such cases are best dealt with at stations which appeal more especially to the natural emunctories—the skin, the bowels, and the kidneys. The skin is stimulated at all spas which possess a bathing establishment. At such places not only the natural thermal waters, but electricity, massage, and other physical devices are employed to increase the activity of this large and unduly neglected excretory organ. Reference has already been made to what may be called the “purgative” spas, of which Marienbad is the type. There remains to be considered those which make a special appeal to the renal output. The best known of these is Contrexéville, in the Vosges mountains, a spa which has for generations enjoyed a world-wide reputation. It is one of a group of three, the other two being Vittel and Martigny, which are situated quite close to one another, and which, having substantially the same kind of water, may be prescribed indiscriminately. Of the three, Vittel is infinitely the most active and enterprising. It has a beautiful bathing establishment, and the accommodation is excellent; but, in comparison with the other two, it is expensive.

Superior in most respects to any of those in the Vosges group is Evian, on the Lake of Geneva. The bathing establishment at this comparatively new and very beautifully situated spa is one of the most completely equipped in Europe, while the waters of the “Source Cachat” promote the activity of the kidneys

in a manner which is truly remarkable. The kidneys being the normal path for the disposal of nitrogenous waste, treatment by "renal" waters, especially when adequately reinforced by bathing, massage, Zander exercise, and due attention to the bowels, is the most satisfactory means of dealing with people who are gouty in an indefinite way. The renal spas are also very conspicuously useful in those who are the subjects of high arterial tension in its functional stage. The "demineralization" of the tissues which such treatment brings about is much more lastingly beneficial than treatment by means of drugs.

SYPHILIS.—This disease is more successfully treated at spas than when the patient is among his ordinary surroundings, just as goutiness is more successfully so treated, namely, because the atmosphere of the spa conduces to that minute observance of detail which in such cases is essential. Mercury is used at the spas by inunction and subcutaneous injection, but chiefly by inunction, the baths and concomitant methods being merely accessory. There is theoretically nothing to be said in favour of spa treatment which may not be urged in favour of similar methods employed at home, but practical experience shows that the results of spa treatment are so immeasurably superior to any other, that it is not too much to say that by neglecting to advise such treatment the physician is not doing his best for the patient. The advantages are not confined to any stage of the disease, though it is naturally in the earliest that the best results are to be expected.

There are four spas which have specialized in this direction: Aix-la-Chapelle (or more properly, Aachen), Wiesbaden, Luchon, and Uriage. The first-named is so immeasurably superior to the others that the only excuse for mentioning them is to supply an alternative for those people (and they are many) who object to go to Aachen for fear that by so doing they may be advertising the nature of their complaint. The choice between Wiesbaden, Luchon, and Uriage must rest upon considerations of fancy and convenience.

ANÆMIA.—There are several stations at which anæmic conditions, especially chlorosis, are very successfully treated. The best known of these are St. Moritz, Schwalbach, and Spa in Belgium. All these places have iron waters charged with carbonic acid gas. They are all very attractive, well-managed stations, at which the physicians are exceptionally experienced. Spa has the advantage of easy accessibility from this country, while in favour of St. Moritz may be urged its great elevation, because, apart altogether from iron waters, high altitudes are very useful in chlorotic states.

RECTAL AND PELVIC CONDITIONS.—It would not be satisfactory to conclude this brief survey without a word about rectal spas and spas which make a special point of the treatment of pelvic diseases in women. The first place to pay any special attention to disorders of the large intestine was Plombières, in the Vosges Mountains. The success which has attended this specialization has secured for Plombières a large number of imitators, none of which have as yet attained to the standard of excellence of their prototype.

The best known "ladies' spa" is Franzensbad, in Germany. There seems to be no particular reason why this station should have specialized in this direction, but the results which are obtained there are such as to justify the great reputation which it now enjoys. Another spa of scarcely less renown is St. Sauveur, in the Pyrenees.

It is well to point out, in conclusion, that by no means the least important matter in the selection of a spa, for whatever purpose, is a wise choice of the physician to whose care the patient is to be entrusted.

Leonard Williams.

HEART, DILATATION OF.—(See MYOCARDIAL FAILURE: SCHOTT-NAUHEIM TREATMENT.)

HEART, FATTY.—(See MYOCARDIAL FAILURE.)

HEART, IRREGULARITY OF.—The majority of patients presenting cardiac irregularity fall into two groups, the characteristics of which must be clearly grasped : (1) Irregularity caused by the appearance of *extra-systoles* ; and (2) Irregularity caused by the presence of *fibrillation of the auricle*. As Mackenzie points out, 60 to 70 per cent of all cases of serious heart failure met with in practice owe the failure directly to this latter condition, or have the failure aggravated by its presence.

1. Arrhythmia due to Extra-systoles.—An extra-systole is a contraction of the heart which occurs before the next beat is normally due, and it originates in some part of the heart other than the sino-auricular node, the normal site of origin.

Apart from the extra-systoles, the action of the heart is regular. The premature systole is less forcible than the normal systole, and may fail to send a perceptible pulse to the wrist, in which case the finger is only aware of a long pause between two normal pulse-waves—an intermission ; or the premature beat may be represented at the wrist by a small but palpable wave.

The incidence of extra-systoles varies greatly. The intermissions may occur infrequently, but sometimes they are so numerous as to simulate the disorderly rhythm of auricular fibrillation.

When every second beat of the heart is premature, we find a “bigeminal” pulse ; when every third, the “trigeminal” pulse. One meets with many individuals in whom the cardiac musculature is abnormally excitable ; they live a healthy, vigorous life, and on examining their heart no disease can be found. In these patients extra-systoles are common, and sometimes cause considerable mental distress. Extra-systoles are also met with in many neurasthenics, or they may result from cardiac strain, from disease of the myocardium, or from toxic influences such as alcohol, tea, coffee, and tobacco. They are frequently found in patients with high arterial tension, arteriosclerosis, or gout. Emotion, excitement, and exertion may precipitate their appearance. They are common in the aged. Gastro-intestinal disturbance and other reflex causes are often exciting factors. In themselves they are not significant ; the gravity of their occurrence is over-estimated ; and unless there is evidence of cardiac disability or structural disease, the patients should be reassured and impressed with the fact that these irregular heart-beats are disagreeable rather than dangerous.

TREATMENT.—There can be no uniform line of treatment. It must be based on the etiology and on the general condition of the patient. All possible reflex causes must be reviewed. The dietary should be carefully considered, and constipation avoided. Dry meals are useful, with sufficient fluid at times which will not interfere with the digestive processes (*see* FLATULENCE and MYOCARDIAL FAILURE).

If in spite of careful dieting the dyspeptic symptoms persist, then some simple stomachic should be ordered.

R Sodii Bicarbonatis	gr x	Aquam Menthæ Piperitæ	ad 3ss
Tincturæ Rhei	℥ij		

One tablespoonful in water before meals.

Ten grains of ammonium bromide may be added to this mixture with benefit in nervous patients.

In the case of toxic influences, endeavours must be made to eliminate them from the system, and as regards chemical substances like alcohol and tobacco, the patient must be advised to cease using them.

In the gouty, strict instructions as to diet are to be laid down, and once a week a blue pill or a dose of calomel should be taken. A morning saline is useful. A mixture such as the following is of value:—

R Potassii Citratis	gr xxx	Infusum Gentianæ Compositæ	
Tincturæ Colchici Seminis	℥viij	(N.F.)	ad 3ss

A tablespoonful to be taken in water shortly before food thrice daily.

If for any reason colchicum is not well tolerated, cachets containing guaiacum resin, in doses of 5 to 10 gr., should be employed.

The irritable and excitable heart muscle of neurasthenia should be braced up by carefully regulated exercise and rest. If extra-systoles are very numerous, and do not respond to the above treatment, then digitalis, in 5-min. doses of the tincture, should be taken thrice daily. In these patients, a mixture containing nux vomica and bromide is also valuable.

R Tincturæ Nucis Vomiceæ	℥xxv	Spiritus Chloroformi	℥x
Ammonii Bromidi	gr x	Infusum Gentianæ Co. (N.F.)	ad 3ss

A tablespoonful in water thrice daily before meals.

2. Arrhythmia due to Auricular Fibrillation.—This must be carefully differentiated from the irregular action due to the occurrence of extra-systoles. The irregularity due to extra-systoles results from the occasional response of the heart to a stimulus originating at some point other than the normal site. In fibrillation of the auricles the condition is entirely different: there is no co-ordinate contraction of the auricular muscle; the whole auricle passes into a tremulous state devoid of driving force. Stimuli are showered down haphazard on to the ventricles from the fibrillating auricles, and the ventricles respond in an absolutely disorderly manner; the stimuli to which they respond are without rhythm, and the action of the ventricles is correspondingly irregular. It is this characteristic lack of any rhythm which enables one to recognize these cases without difficulty. Their recognition is essential in the treatment of patients with irregular action of the heart.

TREATMENT.—The important clinical fact to bear in mind is that, with the onset of fibrillation of the auricle, the work of the heart is at once seriously increased, and therefore the first object of treatment must be to diminish that work so as to give the heart an opportunity to settle down and accommodate itself to its new burden. Rest, slight diminution of the blood-pressure in cases of hypertension, relief of the mental anxiety, and the removal of any detrimental accessory conditions, such as distended stomach or loaded intestine, are all to be aimed at. Drug treatment is to a certain extent tentative. Morphia in small and repeated doses is very valuable where the dyspnœa is distressing, more particularly in patients where there is little if any œdema. Chloral slightly lowers blood-pressure and frequently enables the patient to sleep. There is a widespread and unwarranted fear of this drug. It can be given to those patients for whom morphia has been recommended.

When this disorderly rhythm attacks a patient with mitral stenosis, there is greater hope of effecting an improvement and of slowing the heart by digitalis than in cardiosclerotic patients. In such cases of mitral stenosis suddenly seized with auricular fibrillation, digitalis should be pushed up to the point of producing physiological effects, the object being to depress the conducting power of the auriculo-ventricular bundle. If we are successful, the ventricle receives a very diminished number of stimuli from the auricle, and as a result of this slowing, the diastolic pauses of the ventricle are prolonged, the heart muscle has an opportunity to recover itself, and the circulation becomes more efficient. The mistake which is usually made in the treatment of such cases is to be afraid of the drug. Twenty drops of an active tincture, strengthened if necessary by $\frac{1}{240}$ gr. of digitalin* given four-hourly for the first two days, is

not excessive. The real test of saturation is to be found in the appearance of vomiting and nausea, or marked slowing of the pulse with a coupled rhythm. Such indications suggest the desirability of diminution in the dose, or temporary cessation of the drug. It is a good plan to note the total quantity of digitalis required to produce definite slowing of the heart and relief of symptoms for future reference in the event of a second breakdown. It is perhaps hardly necessary to refer to the necessity of thoroughly purging the patient as a preliminary to treatment by digitalis.

Vomiting occurring during the exhibition of the digitalis series is due to two causes: (1) Local irritation—the stomach resenting the nauseous drug;† (2) Genuine toxic vomiting. In the former the drug should be stopped for twenty-four hours and then resumed again; this is often enough to allay the sickness; or the dose of digitalis may be given well diluted in half a tumblerful of water, or combined with large doses of bismuth. In the latter case the digitalis must be stopped entirely for some days.

When distress is great and the heart dilated and extremely rapid and irregular, the best results are obtained by an intravenous injection of 1 mgm of strophanthin; this can be obtained in sterile ampoules ready for use. Within half an hour of the injection definite relief is often to be observed. The improvement can be maintained either by the administration of strophanthus‡ or digitalis by the mouth. The combination of digitalis with mercury and squills is a valuable method of administration.

Pulveris Digitalis

Pulveris Scillæ
Extracti Hyoscyami āā gr j

This pill should not be given continuously where there is evidence of old kidney trouble.

After the distress associated with the inception of the disorderly action of the heart has passed off, many patients settle down to a comfortable life, but with a definite diminution in their cardiac reserve. Sometimes a small daily dose of digitalis is found necessary to steady the heart. Often, however, the treatment required is general rather than specific; careful attention to the bowels, a somewhat restricted diet, the correction of any anæmia, and moderate exercise may suffice.

Sinus Arrhythmia.—There is a third form of irregular action, common in children and adolescents, and deserving of mention. The irregularity originates at the sino-auricular node, and is dependent on nervous influences. It varies with respiration; and since it is a natural phenomenon occurring in healthy individuals it need cause no anxiety and does not require treatment. (See also HEART, VALVULAR DISEASES OF, and MYOCARDIAL FAILURE.) *John Hay.*

HEART, VALVULAR DISEASES OF.

Chronic Valvular Lesions.—For the purposes of treatment cases of chronic valvular disease may be divided into two great groups:—

1. Cases in which the lesion is so slight that it produces no practical disturbance of the circulation (no symptoms), and those in which the lesion is more severe but is well compensated.

2. Cases in which compensation has broken down, temporarily or permanently.

This division is of the greatest practical importance, and is not always recognized by the practitioner. Some men when they hear a cardiac murmur immediately prescribe digitalis or strophanthus as a matter of routine. This is a grave error, and should be studiously avoided. It is essential to remember

* Larger doses of the tincture would be preferable.—AMERICAN EDITOR.

† According to Hatcher, vomiting following the administration of digitalis is always of central origin.—AMERICAN EDITOR.

‡ Strophanthus is of uncertain action when administered by mouth owing to varying rates of absorption.—AMERICAN EDITOR.

that in the slighter forms of valvular defect, and even in more serious lesions so long as the compensation is well maintained, the heart muscle does not require to be helped by cardiac tonics and stimulants. It is equal to its duties; in such circumstances digitalis and strophanthus are unnecessary and likely to do harm rather than good.

The Treatment of Slight and Compensated Lesions.—The great objects are :—

1. *To prevent Cardiac Strain, and to avoid everything which is likely to Embarrass the Damaged Heart or to Aggravate the Lesion.*—It is important to remember that cardiac strain may be due either to external causes, such as muscular over-exertion, or to internal causes, such as high blood-pressure, the result of gout, kidney disease, etc.

One of the chief difficulties we have in treating cases of cardiac disease is that, in the labouring classes, the patients are often unable to avoid muscular strain, and that, in the upper classes, patients are often unable or unwilling to avoid dietetic and other conditions which tend to produce gout and high blood-pressure.

2. *To keep the Heart Muscle in the highest possible state of Health and Efficiency.*—In trying to carry out this indication, it is important to attend to the condition of the digestive and excretory organs, and carefully and judiciously to regulate the daily life of the patient as regards diet, exercise, sleep, clothing, alcohol, tobacco, tea, etc.

During this, the first stage of the disease, drugs (except perhaps the occasional administration of such remedies as arsenic, strychnine*, and, if the patient is anæmic, iron) are usually not required. Of course, if temporary breakdowns in the compensation occur, the administration of cardiac tonics (digitalis, strophanthus, etc.) is indicated.

Exercise.—It is not always easy to lay down hard and fixed rules as to the amount and kind of exercise which patients suffering from chronic valvular lesions should be allowed to take; but, generally speaking, one may say that out-door exercise, so long as it does not produce shortness of breath, precordial distress, palpitation, or over-fatigue, is eminently beneficial. Walking is for most patients the best form of exercise; walking on the flat is usually better than hill-climbing, but in some cases a carefully regulated plan of hill-climbing, since it necessitates a greater amount of muscular effort and a more rapid flow of blood through the muscles of the body, is beneficial. All violent efforts, such as running to catch trains, lifting heavy weights, riding a bicycle up hill, against a wind, too far or too fast, etc., and excessive or prolonged muscular work which throws an undue strain on the damaged heart, must of course be prohibited.

Diet.—The diet must be carefully attended to. The food should be nutritious and easily assimilated; patients should be cautioned against over-distending the stomach; the amount of fluid which the patient drinks should in many cases be restricted; a dry diet is often best; articles of food which (for the particular patient) are indigestible should be rigidly prohibited, and anything which produces flatulent distention should be avoided. If flatulent dyspepsia is present, appropriate remedies for its relief (such as alkalies before, and carminatives after, meals) should be prescribed.

* *Prescription for Arsenic and Strychnine in combination.*—(It must be particularly noted that if arsenic and strychnine are prescribed in the same mixture, the solution must be *acid*, otherwise the strychnine is precipitated, and a poisonous dose is apt to be concentrated at the bottom of the bottle):—

℞	Liquoris Acidi Arsenosi	3j	Acidi Hydrochlorici Diluti	3ij
	Liquoris Strychninæ (1 per cent)	5ij	Liquoris Peptici (Benger's)	q.s. ad 3iv

M. Sig. : A teaspoonful in water three times daily after food.

If the patient has been accustomed to use alcohol, a strictly moderate quantity may be allowed. A moderate amount of mild tobacco may also be allowed, but over-smoking should be strictly prohibited. Tea and coffee, too, must not be taken in excess. The patient should be warned against over-indulgence in sexual intercourse.

ALKALINE MIXTURE FOR CASES OF DYSPEPSIA.

CARMINATIVE TABLOID FOR FLATULENCE.

Burroughs & Wellcome's soda-mint tabloid, which contains sodii bicarb. gr. iv, ammon. carb. gr. $\frac{1}{2}$, ol. menth. pip. q.s., is an excellent carminative. Two, three, or more tabloids should be swallowed (not sucked) half an hour after food or when the flatulence is troublesome.

MENTHOL MIXTURE FOR FLATULENCE.

R Menthol	gr. iv	Spiritus Chloroformi	āā 3j
Spiritus Ammonię Aromatici			

M. Sig. : A teaspoonful in water when required.

NOTE.—The menthol is precipitated when the mixture is added to water, but in a very fine state of division.

It is of great importance to attend to the condition of the great depurative organs (the intestine, the liver, the kidneys, and the skin), for the defective removal of waste products is apt to poison the blood, to interfere with the perfect nutrition of the organs and tissues, including the heart muscle, and to lead to high blood-pressure. Constipation and straining at stool are to be avoided ; the patient should see that he has a sufficiently copious evacuation of the bowels every day. Cascara, aloin, tamar indien, or some other suitable laxative should, if necessary, be taken every night. In gouty cases, or where there is high blood-pressure, a watery purge may be given once or twice a week with advantage.

An abundance of sleep and a long rest in bed are in many cases eminently serviceable. Care should be taken that the bedroom is well ventilated and not too hot. A sufficiency of sleep is essential for the due nutrition of the nervous system, the healthy condition of which is one of the most important factors in maintaining the healthy functional activity and nutrition of the tissues and organs of the body, including the heart muscle.

Overwork, and particularly worry, should, if possible, be avoided ; rest, recreation, frequent and long holidays, are to be recommended ; a continuous strain, whether of body or mind, is prejudicial. The subjects of chronic valvular disease should be told in a judicious and tactful way that their hearts are not sound (care being taken, of course, not to frighten them), that they must regulate their lives accordingly, and that they are not able to take liberties with themselves. In selecting a suitable occupation for a young person affected with a chronic valvular lesion, these facts must be kept in view.

All conditions likely to induce a fresh attack of endocarditis (such as acute rheumatism), or which throw a strain upon the damaged heart (such as acute

bronchitis), must be carefully guarded against. The subjects of chronic valvular lesions should be well clothed and well housed; they should wear flannel or silk next the skin. Intercurrent attacks of rheumatism, bronchitis, influenza, common cold, etc., however slight, should be carefully treated.

Such are the general principles which should guide the practitioner in the treatment of the slighter forms of chronic valvular disease and of the more severe forms during the period of satisfactory compensation. It is surprising how long some cases of this kind continue without the development of active symptoms, more especially in private practice.

The Treatment of Temporary Breakdowns of Compensation.—Temporary breakdowns of compensation, in which acute embarrassment and failure of the heart are the result of undue effort, excessive strain, or the development of some intercurrent complication, are of frequent occurrence during the course of chronic valvular lesions. In chronic mitral lesions, for example, an acute attack of bronchitis which throws an increased strain on the right heart, is frequently attended with the rapid development of serious symptoms (marked shortness of breath, cyanosis, œdema of the feet, etc.). In such circumstances the bronchitis must, of course, be treated by appropriate remedies; but an all-important point is to aid the enfeebled right heart by the administration of cardiac tonics and stimulants. Digitalis is at this stage of the case an invaluable remedy. In some cases in which the right heart is greatly engorged the strain is best relieved by venesection. In many cases of chronic valvular disease in which acute pulmonary lesions with failure of the heart are developed, I have found great benefit from subcutaneous injections of strychnine (from 2 to 4 min. of the 1 per cent solution, every six or eight hours) and oxygen inhalations. It is unnecessary to say that, during temporary breakdowns of compensation, complete rest in the position which is most agreeable to the patient, and very careful feeding, are essential; purgatives, diuretics, antispasmodics, narcotics, and sedatives may also be required, as in the more advanced stages of chronic valvular lesions. As soon as the compensation is again restored, the digitalis or strophanthus may be altogether discontinued, or given in much smaller doses, or alternated with such remedies as arsenic, strychnine, and general tonics. After convalescence from such temporary breakdowns, a carefully regulated course of Nauheim treatment or of Oertel treatment is often beneficial.

The Treatment of Chronic Valvular Lesions after the Breakdown of Compensation.—In those cases of chronic valvular disease in which the lesion is actively progressive, or so severe that the compensation is unable to balance the lesion, a time ultimately, and often speedily, arrives when more active and energetic treatment is required. It is at this stage of the case that digitalis and strophanthus are especially valuable, in conjunction with other measures calculated to relieve the secondary results and complications, such as dropsy, and engorgement of the lungs, digestive organs, and kidneys, which are due to the failure and embarrassment of the circulation. Digitalis is useful in almost all cases and in all forms of chronic valvular disease, but especially in cases of mitral disease, with irregular and feeble pulse, dropsy, scanty, high-coloured, and (often) albuminous urine. In my experience digitalis is more useful, and can be given in larger doses and continued for much longer periods of time, in mitral than in aortic regurgitation. When digitalis fails, or if it should for any reason be contra-indicated (in consequence, for example, of idiosyncrasy* on the part of the patient, the development of vomiting, etc.), some other cardiac tonic, such as strophanthus, caffeine, etc., must be employed. In many cases of chronic valvular disease there is no marked benefit until the full physiological effects—copious diuresis and slowing of the pulse—of the drug (digitalis) are produced. Several days may be required before these full effects occur.

* Idiosyncrasy to digitalis has never been observed by the American Editor.

If small or moderate doses of digitalis (5 to 10 min.) do not relieve the symptoms and produce marked benefit, the dose should be increased, unless, of course, for any reason large doses of the remedy (such as 15, 20, or 30 min. of the tincture) seem to be contra-indicated. Over and over again I have seen the most striking benefit result from the administration of large doses of digitalis when small doses (5 to 10 min., three or four times daily) produced little or no benefit.

In the later stages of chronic valvular lesions (i.e., after the compensation has more or less permanently failed), rest is essential; the patient should be allowed to rest (lie or sit) in the position which is most agreeable to him. In cases of this kind the stomach and liver are often engorged, the digestive powers impaired, and the feeding of the patient a matter of difficulty. The diet should be of the lightest kind, and yet as nutritious as possible. Care must be taken to avoid over-distention of the stomach, and to prevent and allay flatulent distention. Dyspeptic symptoms must be carefully treated. In aggravated cases of this kind, I have seen marked benefit from rectal feeding;* by means of rectal feeding, and giving nothing, not even water, by the mouth, the stomach is kept empty, and the flatulent distention, which is in many of these cases a most important cause of cardiac embarrassment, altogether avoided—over and over again I have seen the apex beat which was displaced far outwards to the left return to the normal, or almost to the normal, position, after a week or ten days of rectal feeding. As the result of rectal feeding the engorgement of the venous system is in some degree lessened, the cardiac strain is relieved, and the dilatation of the cardiac cavities becomes materially lessened. The altered position of the apex beat after a course of rectal feeding is partly, I think, due to collapse of the stomach (a mechanical result) and partly to contraction of the heart itself (a most important vital result). The improvement in the general condition of the patient and in the relief of distressing cardiac symptoms which results from rectal feeding in cases of this kind is often most striking, and is in many cases the starting-point of long-continued, and in some cases of lasting, improvement. At this stage of the disease, dropsy and lung affections are often distressing complications, and require to be met by purgatives, diuretics, massage, and other appropriate therapeutic measures. A salt-free diet seems useful in some cases in which dropsy is a prominent feature.

In those cases of chronic valvular disease—and they are chiefly cases of mitral regurgitation—in which a fatty condition of the cardiac muscle, the result of anæmia, is present, iron (in the chlorotic type) and arsenic (in the pernicious type of anæmia) are by far the most important remedies. In cases of this kind, digitalis and strophanthus are usually, I think, useless, and often harmful.

In those cases in which there is reason to suppose that the valvular lesion is complicated or associated with fatty infiltration and a dilated, flabby heart, careful regulation of the diet and bowels, plenty of fresh air and carefully regulated exercise, together with arsenic and strychnine, are the remedies which I chiefly employ. In this type of case, the Nauheim and Oertel plans of treatment are often beneficial. It is, however, always advisable to proceed cautiously and tentatively, and to watch the effect of the exercise and remedies employed; for, in cases of this kind, it is often difficult or impossible to exclude organic conditions of a more serious nature, such as grave myocardial degeneration due

* NUTRIENT ENEMATA.—The nutrient enema which I am in the habit of prescribing consists of two ounces of peptonized milk, half an ounce of raw beef juice or of Wyeth's meat extract, and a raw egg. If necessary, a little brandy may be added. If the rectum becomes irritable, as it often does after prolonged rectal feeding, and if the enemata are not retained, a small quantity of laudanum (8, 10, or 12 drops) may be added to every third or fourth enema. I usually prescribe one nutrient enema every eight hours; and, in some cases, also order a nutrient suppository every eight hours, so that the patient has a nutrient enema and suppository alternately every four hours.

to disease of the coronary arteries. When there is advanced organic disease, and particularly when marked degeneration of the cardiac muscle is present, the Nauheim and Oertel plans of treatment require, if employed at all, to be conducted with great care and caution.

In cases of chronic valvular disease associated with high blood-pressure and tightly constricted vessels, the essential objects of treatment are to relieve the cardiac strain, to reduce the blood-pressure, and to tone up the enfeebled heart. The diet must be carefully regulated, the amount of fluid which the patient drinks restricted, and the blood-pressure reduced by saline purgatives and the administration of iodide of potassium or nitrites (nitrite of sodium, nitroglycerin, etc.). Iodide of potassium with arsenic is, I find, a very valuable combination in these cases. In cases of this kind I usually prescribe strophanthus in preference to digitalis. If the patient is gouty, salicylate of sodium, bicarbonate of potash, piperazine, and a course of treatment at Carlsbad are often useful.

In those cases in which there is reason to believe that the valvular lesion is associated with chronic myocarditis and fibroid degeneration, arsenic, strychnine, digitalis, and, in some cases, iodide of potassium, are, in my experience, the most useful drugs.

In those cases in which angina-like pain is associated with a chronic valvular lesion, the appropriate treatment for angina pectoris must be employed. In dealing with these cases it is of importance to draw a distinction between those in which the blood-pressure is high and those in which it is low. In the former, nitrite of amyl, nitroglycerin, erythroltetranitrate, and nitrite of sodium, and in the latter, diffusible stimulants and subcutaneous injections of morphia are, in my experience, the best remedies.

The Treatment of Symptoms and Secondary Results.—In the later stages of chronic valvular lesions, the treatment has largely to be directed to the secondary derangements and complications in the lungs, stomach, liver, intestinal tract, kidneys, brain, subcutaneous tissues, and internal cavities. Many of the most important of these derangements and complications, such as dropsy and dyspepsia, are the result of chronic venous engorgement and impaired cardiac power. In dealing with dropsy in the subcutaneous tissues and internal cavities, and other symptoms of this kind, cardiac tonics—more especially digitalis, which, I need not say, is in such cases the best diuretic which we possess—careful regulation of the diet, restriction of the amount of fluid which the patient drinks, watery purges, diuretics, massage, and, in some cases, the mechanical removal of dropsical fluids, are the most important means of treatment.

Hæmoptysis occurring during the earlier stages of mitral stenosis, i.e., when the lesion is satisfactorily compensated, is beneficial rather than the reverse, and does not require any active treatment. Hæmoptysis occurring in the later stages of chronic valvular lesions, the result of pulmonary apoplexy and dilatation and failure of the right heart, is of serious significance, and calls for the active administration of digitalis or other cardiac tonic.

Hemiplegia and other conditions due to embolism occurring in the course of mitral stenosis and other forms of chronic valvular disease, and septic endocarditis, which is especially apt to occur in cases in which the valvular apparatus of the heart is affected with chronic disease, have to be treated in accordance with the principles laid down in other parts of this work.

I conclude this article by briefly summarizing my experience as to the value of some of the different measures and remedies employed in the treatment of chronic valvular lesions.

Rest.—In cases of chronic valvular disease with failing or ruptured compensation, rest (more or less complete in accordance with the special peculiarities

of different cases) is, in my opinion, the most important means of treatment which we possess.

Exercise.—This is a very valuable means of treatment in many cases, more particularly during the first stage of valvular lesions, in those cases in which the myocardium is fairly healthy, in which the valvular lesion is associated with neurotic disturbance, and in which the heart muscle is flabby or debilitated as the result of some temporary cause, such as an attack of influenza. In many cases of aortic and mitral disease, in the less severe forms of senile heart, and in the slighter forms of myocardial degeneration, judiciously regulated walking exercise is invaluable, so long as the compensation is well maintained.

By muscular exercise we are enabled to promote the condition of the general health and of the cardiac health, to hasten the circulation through the peripheral organs and through the heart itself, and to prevent stasis and engorgement with all their disastrous results. So long as exercise does not produce marked shortness of breath, over-fatigue, or other untoward symptoms, it should, I think, be not only permitted but encouraged.

Oertel's Plan of Treatment and the Nauheim Method of Treatment (exercise against resistance and aerated brine baths).—These are, I think, chiefly valuable in the same class of cases (valvular disease in which the cardiac muscle is reasonably sound). In advanced stages of valvular disease, and in cases in which the valvular lesion is associated with marked atheroma, grave degeneration of the cardiac muscle, aneurysms of the aorta, and angina pectoris, these methods of treatment are often harmful and, in some cases, dangerous. (See also SCHOTT-NAUHEIM TREATMENT.)

In the Oertel and Nauheim methods of treatment, careful regulation of the diet and the amount of fluid which the patient is allowed to drink is an important factor in the treatment.

Mental Therapeutics.—I attach the greatest importance to sustaining the mental tone of the patient and encouraging him to hope that the treatment will be attended with success. A favourable opinion confidently expressed has often a most beneficial effect, more particularly in those cases in which the valvular lesion is well compensated, associated with a nervous and irritable condition of the heart, or in which the patient is of an anxious, nervous temperament.

Iron.—This is an invaluable remedy in those cases in which the valvular lesion is associated with, or due to, deficiency of hæmoglobin (the chlorotic type of anæmia); the preparation of iron which I like best in cases of this kind is the Blaud-pill capsule (one, two, or three No. 3 capsules, three times daily).

Arsenic.—This is a valuable cardiac tonic in many cases of valvular disease, more especially during the first stage, in cases in which a temporary breakdown of compensation has been recovered from under the administration of digitalis or other cardiac tonics, and in many cases in which there is angina pain, and fatty or fibroid degeneration. Speaking generally, I find arsenic is more useful in aortic than in mitral cases.

Strychnine.—This I consider is one of the most useful remedies which we possess. I find it very valuable in many cases of valvular disease before there has been a decided breakdown of compensation; in these cases I often give it in combination with arsenic. Strychnine is also very useful in some cases during temporary breakdowns of compensation, especially when there are bronchial or other pulmonary complications; in cases of this kind I rely chiefly on subcutaneous injections of strychnine, inhalations of oxygen, and digitalis or strophanthus.

Digitalis.—It is unnecessary to say that this is by far the most valuable cardiac tonic we possess, both for the purpose of producing immediate and lasting effects—tiding the patient over acute complications, and permanently

sustaining the cardiac power and preventing further breakdowns of compensation. I agree with those who think that digitalis is more useful in mitral than in aortic cases; it is especially valuable in cases of mitral regurgitation with dropsy, quick, irregular, or intermittent pulse, scanty, high-coloured urine loaded with urates, etc. In cases of this kind, the dose should be increased until the full physiological effects (slowing of the pulse, diuresis, etc.) are produced. Digitalis should be given more cautiously, and for shorter periods of time, in cases of aortic regurgitation; in cases of this kind it cannot be expected to produce, and as a matter of fact does not produce, such satisfactory results as in those of mitral regurgitation. When mitral regurgitation is superadded to aortic disease, digitalis is often very useful. Digitalis should, I think, be cautiously given in cases in which there is reason to suppose that the cardiac muscle is markedly fatty; it is beneficial in some cases in which there seem to be chronic myocarditis and fibroid degeneration. Where the pulse tension is high, I usually prescribe strophanthus in preference to digitalis. In such circumstances, if digitalis is given, I usually combine it with iodide of potassium, salicylate of sodium, or some remedy—such as nitroglycerin or nitrite of sodium—which reduces blood-pressure.

I usually give digitalis in the form of tincture (6 to 35 min.) or infusion ($\frac{1}{4}$ oz. to $\frac{1}{2}$ oz.); the powder given in the form of pill ($\frac{1}{2}$ to 2 gr.) is also an excellent preparation; in some cases, Nativelle's granules (1, 2, or 3 in the twenty-four hours) are undoubtedly most valuable, more especially in cases in which it is necessary to produce the full effect of the remedy with rapidity, and in some cases in which the liquid preparations of digitalis produce vomiting and gastrointestinal derangement.

Strophanthus.—I usually prescribe strophanthus (1 to 5 min. of the tincture) in preference to digitalis in those cases of chronic valvular disease in which the blood-pressure is increased, in cases in which one wishes to produce a rapid effect, and in which digitalis, owing, perhaps, to some idiosyncrasy of the patient, disagrees.

Caffeine.—This is a valuable cardiac tonic, and should be tried when digitalis and strophanthus fail (dose, 3 to 10 gr. of the citrated, three times daily).

Alcoholic, Ammoniacal, and Ethereal Stimulants are of great use for the purpose of relieving urgent symptoms and warding off asystole. In those cases in which there is vomiting, brandy and champagne are, I think, the most useful forms. Of recent years I have prescribed alcohol much less freely than I formerly did.

Oxygen Inhalations.—Inhalations of oxygen are, I think, of great value in some cases of chronic valvular disease in which respiratory difficulties are prominent, especially where there is bronchitis, pneumonia, or pulmonary apoplexy.

Iodide of Potassium (5 to 20 gr., three times daily).—This is a very valuable remedy in some cases of aortic disease, in valvular lesions associated with angina pectoris, mitral regurgitation associated with high blood-pressure, gouty conditions, and in cases in which there is reason to suspect that the valvular lesion or the arterial disease which is associated with it is the result of syphilis.

Salicylate of Sodium (5 to 20 gr., three times daily).—This is a remedy which I often prescribe in valvular lesions associated with gouty and rheumatic symptoms.

Nitroglycerin (1 to 3 drops of a 1 per cent solution), *Nitrite of Amyl* (3 to 5 drops by inhalation, repeated if necessary), *Erythroltetranitrate* ($\frac{1}{2}$ to 1 gr.), and *Nitrite of Sodium* ($\frac{1}{2}$ to 3 gr.).—These remedies are very valuable in cases in which valvular lesions are associated with high blood-pressure or angina pectoris.

Menthol.—This remedy is very useful in many cases in which flatulent distention of the stomach occurs in the course of valvular lesions. I usually give $\frac{1}{8}$ gr.

or $\frac{1}{4}$ gr. of solid menthol dissolved in $\frac{1}{2}$ dr. of spirits of ammonia and $\frac{1}{2}$ dr. of spirits of chloroform for a dose.

Rectal Feeding.—In several cases of advanced valvular disease with ruptured compensation, and in some cases of dilated heart apparently due to chronic degeneration of the cardiac muscle, I have seen marked benefit result from rectal feeding. The contraction of the stomach and the disappearance of the flatulent distention seemed to be the chief factors in the production of this improvement.

Purgatives—especially mercurials and salines—are, it is needless to say, most useful in many valvular lesions, especially in mitral cases attended with dropsy, and in cases in which the right side of the heart is over-distended and the tissues are engorged and water-logged.

Diuretics.—In many cases in which the urine is scanty, more especially in mitral regurgitation with dropsy and in the advanced stages of ruptured compensation with dropsy whatever the nature of the valvular lesion, diuretics are of great value: digitalis, strophanthus, caffeine, theobromine sodium salicylate (10 to 40 gr.), a combination of digitalis, squill, and mercury, the salts of potash (bitartrate, acetate, citrate, 20 to 30 gr.), and the nitrites (such as nitrite of sodium $\frac{1}{2}$ to 3 gr.) are some of the most useful drugs.

The Mechanical Removal of Dropsical Effusions.—In the advanced stages of many cases of valvular disease, the removal of dropsical fluid from the internal cavities, especially from the pleura and peritoneum, is sometimes attended with marked benefit. I never puncture the dropsical legs or scrotum, either by simple puncture or by means of Southey's tubes, until other measures have been fully tried and have failed to give relief.

Massage.—When subcutaneous dropsy is present, this is often a useful means of treatment; it aids the venous and lymphatic return, and quickens the circulation in the muscular and peripheral tissues of the body. It is also of great use in many cases of valvular disease unattended with dropsy, in which, owing either to the nature of the lesion, the presence of shortness of breath, or other symptoms, ordinary muscular exercise is contra-indicated.

Venesection.—This is undoubtedly valuable in some cases in which the right heart is greatly over-distended and engorged, and is particularly useful, I think, when the engorgement depends upon temporary lung complications, superadded to mitral disease.

Dry Cupping.—This is useful in some cases for the relief of congestion of the lungs and other pulmonary and kidney complications.

Sedatives and Soporifics.—The soporifics which I chiefly use are trional (10 to 30 gr.), chloral formamide (10 to 30 gr.), paraldehyde (1 to 4 dr.), and morphia ($\frac{1}{8}$ to $\frac{1}{2}$ gr.). Sulphonal (10 to 30 gr.) is, I think, less certain in its action than chloral formamide. I seldom give chloral hydrate in grave cardiac cases, on account of the marked depression which it is sometimes apt to produce. Paraldehyde is often very useful, especially, I think, in cases associated with bronchitis or other pulmonary complications, and in which morphia is contra-indicated. After the breakdown in compensation, and in the distressing restlessness, dyspnoea, and orthopnoea of advanced valvular lesions, small and frequently repeated doses of opium ($\frac{1}{2}$ to 1 gr.) or morphia ($\frac{1}{8}$ to $\frac{1}{2}$ gr.) are invaluable. The presence of albumin in the urine and of kidney disease is not, in my experience, a contra-indication, though in such conditions morphia and opium must, of course, be employed with caution. Morphia should not be given when there is œdema of the lungs or much bronchial secretion. (See also MYOCARDIAL FAILURE and SCHOTT-NAUHEIM TREATMENT.)

HEAT APOPLEXY.—(See SUNSTROKE.)

HEMIPLEGIA.—In this article, the condition rather than its causes will be dealt with. Reference will be made almost entirely to cases of ordinary hemiplegia dependent upon a vascular lesion which has damaged some portion of the motor tract, from the cortex to the base of the brain; and remarks as to treatment will not apply to hemiplegia due to neoplasm, meningitis, or abscess. In the latter cases, treatment can aim only at removal of the cause, though, if this can be accomplished successfully, the question of treating paralysis resulting from the original lesion may still arise.

In all cases it will be assumed that we are dealing with hemiplegia caused by vascular lesions, hæmorrhagic, embolic, or thrombotic, and that the causes of these conditions, such as arteritis, specific or otherwise, valvular heart disease, nephritis, anæmia, and other diseases of the blood, receive attention. The gravity of any of these conditions may render treatment of resultant hemiplegia quite a secondary consideration, for any active treatment of hemiplegia in a subject with one foot in the grave would only accelerate his downward progress.

Treatment of hemiplegia itself is unavailing, or unsatisfactory :—

1. When it is due to neoplasms or abscess.
2. In elderly broken-down subjects of advanced Bright's disease, widespread atheroma, diabetes, severe valvular heart disease.
3. In cases of progressive cortical softening, with mental changes.
4. In cases of long-standing hemiplegia, in which there is evidence of complete degeneration of a considerable portion of the motor tract.

TREATMENT.—Many patients are not treated at all. Doubtless they receive plenty of iodide of potassium, strychnine, and other drugs; but so far as the paralysis is concerned, they are too often left to themselves. The blame for this rests partly on the public. Paralysis, to the public, means incurability; a rooted conviction prevails that a person who has had one stroke of paralysis is bound to have another, and yet a third, which will be infallibly fatal. Medical attendance is therefore discouraged as useless, and the medical attendant soon receives a more or less polite intimation that his visits need not be continued, and that he will be "sent for if wanted"—that is to say, for incidental ailments, or should the patient have another stroke, and appear at death's door. Neglect of hemiplegic patients may be attributed also to the pessimistic teaching that those who get well do so without treatment, and those who do not get well derive no benefit from treatment. Neither statement is strictly true. Mild cases may never recover unless treated; and severe cases, unless treated, may go from bad to worse. It must be freely admitted that, unfortunately, little or nothing can be done for a patient when the greater part of one of his motor tracts has been totally destroyed; yet the existence of such destruction should not be too readily assumed. Its presence may be simulated by a purely functional inability to make use of the powers which have been actually restored. Many a patient who is admitted to hospital complaining that his arm and leg have been absolutely useless for months, discovers, when the fact is pointed out to him, that the limbs are not so powerless as they seemed, and from that time daily makes fresh discoveries which cheer him.

In a severe case of hemiplegia of from six to twelve months' duration or longer, the patient's arm and leg may be quite useless and immobile. He is unable to stand or walk. His joints are fixed, and any attempt to move them causes extreme pain; his shoulder is usually adducted to his side, his elbow and wrist are flexed, his forearm is pronated and held across his chest, and his fingers and thumb are doubled into the palm of his hand. His hip and knee also may be flexed, though more commonly extended, his thigh adducted, his knee and foot inverted, and his heel drawn up. The muscles are all wasted, and some are shortened and contracted, thus causing the characteristic pose of

the limbs which cannot be overcome, and the tendon reflexes are exaggerated. There may be œdema, lividity, pain, tenderness, and hyperæsthesia of the limbs.

This is the extreme and incurable state of helplessness at which the sufferer from hemiplegia may arrive. The immobility of the limbs is due (1) To articular adhesions ; (2) To motor paralysis leading to muscular atrophy ; and (3) To spasticity or spasmodic contraction of certain muscles, leading to permanent shortening of those most affected. These conditions in an advanced stage are incurable ; but I submit that systematic and intelligent treatment from the first would lessen the number of incurable patients, and would alleviate the lot of those not cured.

Besides these far advanced and perhaps irremediable cases, we meet with others in which disablement is only partial. In the majority it is the arm which remains helpless. Sometimes it is in the condition already described, sometimes—long after a stroke has occurred—the limb remains powerless, wasted, and flaccid, though spasticity is absent. These are frequently most amenable to treatment, and to them further allusion will be made.

It is important to grasp the fact that the great majority of cases of hemiplegia tend towards an at all events partial recovery. Yet such recovery is rarely spontaneous in lethargic, despondent, and timid subjects. These must be taught to realize the power which they have regained but do not use.

Functional or Hysterical Paralysis supervening on genuine Hemiplegia.—Sometimes, long after structural damage causing organic hemiplegia has been repaired, one limb, usually the arm, remains absolutely powerless. It dangles loosely at the patient's side, and when he wishes to alter its position, he will pick it up with his sound hand and throw it carelessly on his knee, or on the table, as desired. The limb may be slightly wasted, cold, and all forms of sensation may be blunted. The tendon-jerks are active. Rigidity is entirely absent, but on manipulating the limb, and performing rough unexpected passive movements, the muscles will be felt to contract slightly in resistance, and then become flaccid again as before. There may or may not be restriction of fields of vision and other hysterical stigmata in such cases, but the condition described is suggestive of the functional nature of the paralysis, and is usually promptly cured by a few applications of the electrical wire brush.

More frequently such cases enlarge the roll of miracles performed at the shrines of saints and quacks. It should be remembered that functional disablement may outlast organic lesions.

EXPERIMENTAL EVIDENCE OF THE EFFICACY OF TREATMENT OF HEMIPLEGIA IN ANIMALS.

The physiological interest of an experiment on animals sometimes overshadows its practical value from the clinician's point of view. For this reason it may not be out of place to refer to the well-known observations of Prof. C. S. Sherrington, on the results of treatment of monkeys after paresis of limbs has been induced by destruction of the motor cortex. He has stated that in monkeys the effects of total or very large ablations of the Rolandic area are as follows : "The limbs become permanently flexed at elbow or knee, the shoulder and hip being adducted, the ankle flexed. This phenomenon usually begins about a month after healing of the wound. Its onset is hastened by want of exercise by the paretic limb. If the animal be encouraged to use it freely, and in roomy surroundings, or if passive gymnastics are practised, this form of contracture may be indefinitely postponed, and in early stages arrested. The fibres of the affected muscles degenerate after a time ; the degeneration affects the stretched extensors more than the contracted flexors ; the atrophy is the result of the inactivity " (*Clifford Allbutt's Syst. of Med.*, vol. vi., p. 517).

This interesting observation, that in the monkey post-hemiplegic rigidity and atrophy may be indefinitely postponed, or even arrested, in early stages, by passive and active exercises, encourages the employment of similar methods in the case of human beings. This illustration might be used as the text of the remarks which follow.

THE METHODS OF TREATMENT at our disposal are :—

(1) *Passive Movements*; (2) *Mechano-therapeutics*; (3) *Massage and Electricity*; (4) *Re-education of Movements* by passive and active exercises, combined with encouragement and suggestion.

It will be convenient to consider these modes of treatment in connection with the conditions which they are designed to remedy.

SPASTICITY OR RIGIDITY.—Hemiplegic rigidity is described as “initial,” “early,” and “late” or “structural.”

Initial Rigidity occurs at the onset of the lesion, and usually lasts but a few hours.

Early or Secondary Rigidity comes on after the lapse of a few days, weeks, or even months. It varies in degree, being often less marked, or even absent, after rest. It is increased on voluntary use of the limbs on the unaffected side. It may disappear when the patient yawns.

Late or Structural Rigidity is the ultimate result of prolonged early rigidity. It consists in permanent shortening of certain muscles, and is practically incurable. Hence it is of the greatest importance to endeavour to prevent its occurrence.

The Causation of Rigidity is still obscure. Both initial and early rigidity have been ascribed to direct irritation of the descending motor tract by the lesion. The more generally accepted theory is that it is due to unantagonized cerebellar influence, as suggested by Hughlings Jackson. This is supported by the fact that when descending sclerosis of the motor tract has taken place, the tendon jerks are exaggerated, showing that the normal inhibitory control of the cerebral cortex is annulled.

The muscles chiefly and usually affected are, the adductors of the shoulder, the flexors of the elbow, the pronators of the forearm, the flexors of the fingers and thumb, and the adductors and opponens muscles of the thumb. In the lower extremity, the adductors (rarely the flexors) of the hip, the hamstrings, the plantar flexors and invertors of the foot are specially involved. Spasmodic rigidity of these muscles causes the characteristic flexion, with adduction and inward rotation, of the affected limbs in hemiplegia.

FLEXIONAL ATTITUDE.—The explanation usually given of the characteristic pose of the limbs is that the stronger muscles overcome their weaker opponents; but this is not quite satisfactory.

Horsley and Löwenthal have shown that, in an animal rendered de-cerebrate by severance of the crura cerebri, stimulation of the cerebellum causes contraction of the biceps and active relaxation of the triceps (Mott, *Arch. of Neurology*, vol. ii., p. 316).

It seems, therefore, that the most probable explanation of the flexional attitude in hemiplegic rigidity is that cerebellar influence is chiefly over the muscles which undergo contraction, whilst cerebral influence over the opponents of these muscles is cut off by the lesion. Whatever may be the explanation, the facts afford a guide to treatment. The sooner early rigidity appears, the less favourable is the prognosis, and vice versa. As a rule, if rigidity, after three months from the onset, is absent, whilst the limb remains flaccid, yet powerless, the disability is probably largely functional, though to this there are exceptions.

1. Passive Movements.—*Articular adhesions* frequently cause limitation of movements. They may occur in the elbow, the wrist, the hip, the knee, and the ankle, but are most common and are formed earliest in the shoulder, rendering movements of the joint painful, if not impossible. A limb which might have recovered is often useless owing to their presence. Some regard adhesions as trophic, others as rheumatic, in origin. In advanced cases, changes indistinguishable from those of rheumatoid arthritis may be induced, especially in patients who already have signs of that disease. The nerves in the neighbourhood of the joints may be involved, and give rise to the painful symptoms of peripheral neuritis. Whatever be their cause, in many cases adhesions are preventable. Unfortunately, it happens too often that in early days of hemiplegia a dread is entertained lest any disturbance of the patient should cause further hæmorrhage or other mischief in the brain. So he is left to cuddle and caress his paralyzed arm to his heart's content. He usually hugs it to his side, and flexes his elbow and forearm across his chest in the very position it is desirable to avoid. This fear of moving the limbs is quite unfounded. Gentle passive movements of each joint should be practised many times a day from the very first; for adhesions begin to form very early in the first week or two, during which it is advisable to confine the

patient to bed. When formed, they are difficult to disperse; hence the importance of preventing their occurrence, or dealing with them early. Neglected adhesions soon become permanent. Arthritic adhesions are, however, often absent, and fixation of joints is due solely to muscular contraction.

Treatment of Early Rigidity.—The early treatment of this condition is as important as is that for the prevention of articular adhesions. Almost from the first the limbs tend to assume the attitude which may afterwards become permanent. Therefore, even whilst the patient is confined to bed, all faulty positions and any tendency to adopt a particular position should be corrected. Adduction of the shoulder may be prevented by placing a sand-bag in the axilla. The elbow should be kept extended rather than flexed; the tendency to flexion is easily overcome in early stages. Advantage may be taken of the curious consolation which the patient derives from playing with his paralyzed arm, by instructing him to alter its position himself from time to time with his sound hand. Faulty positions of the lower extremity should be similarly treated. The limb should be rotated outwards and abducted, and the foot dorsiflexed and everted, in order to obviate the tendency to assume opposite positions. Spasm of the hip flexors is rare, but when it occurs it may be counteracted by placing a pillow beneath the buttocks. Contraction of the hamstrings should be treated by raising the heel. Sand-bags may be used to ensure favourable position of the limbs. When the patient leaves his bed, similar precautions should be taken against malposition. He should never be allowed to carry his arm in a sling, but should keep it dependent as far as possible, only flexing it from time to time should œdema appear. He should not be allowed to sit with his knees and toes turned in, but should be told to correct these positions himself. The first principles of treatment, therefore, aim at prevention of fixation of joints and faulty positions of limbs.

Muscular Atrophy usually occurs sooner or later in hemiplegic limbs, and is always more marked in the upper than in the lower extremity. (In cases of post-hemiplegic violent athetoid movements, however, the muscles may become even larger and more powerful than those on the unaffected side.)

It is said that muscular wasting does not occur until late or structural contracture appears; but although certainly most marked in the latter condition, it may be present in earlier stages.

Muscular wasting in *early* hemiplegia is most commonly associated with coldness or lividity of the limb, and with some diminution of electrical reactions. Rigidity is usually less apparent, and the tendon reflexes are less active than in cases where muscular nutrition remains unimpaired. These conditions suggest implication of the anterior cornual cells. Yet these are not directly affected by a cerebral lesion, except in so far as cerebral impulses are cut off from them. This may, indeed, according to Charcot, produce degenerative changes in the anterior cornual cells, but most probably muscular atrophy, and other symptoms pointing to implication of the cornual cells, are due to disuse of the limbs. For it must be remembered that not only muscular but nervous tissues suffer from disuse.

Mott and others have shown that the neurons are dependent on stimuli from the periphery for their function and nutrition, such stimuli being derived from normal movements and alterations in tension of the skin, muscles, tendons, and ligaments. The lower motor neurons may suffer, and their functional vitality may be lowered, owing to absence of normal peripheral stimuli. Hence, if normal stimuli be prevented by disuse of the limbs, artificial stimuli must take their place. Passive movements, massage, and electricity are such artificial stimuli. By them we may hope to preserve the nutrition of muscles and neurons alike. If we can do so, it is obvious that the patient will be better able than otherwise to make use of the gradual return of power expected in most cases of hemiplegia.

Passive movements may aid as stimuli to the lower motor neurons, as well as in the prevention of articular adhesions.

Some corroboration of the view that functional affection of the lower motor neurons may retard recovery in hemiplegia is afforded by the fact that electrical treatment is always most useful in cases of diminished electrical excitability.

Another cause of hemiplegic muscular atrophy is neuritis, usually due to inflammatory changes in and about the joints, especially the shoulder-joint, causing adhesion and

exudation in which the nerves are involved. Such conditions are often extremely painful. The skin may become glossy and exquisitely tender in places, and the electrical responses may be lowered, or show reaction of degeneration.

Treatment in advanced stages of these serious complications of hemiplegia can only be palliative. The pain may be relieved to some extent by painting the limb with equal parts of camphor and chloral hydrate, or glycerin and belladonna. Sometimes mild galvanism is of service.

Hysterical paralysis, as previously mentioned, should be borne in mind when wasting and powerlessness coincide with flaccidity, long after rigidity might have been expected. In such cases, electrical excitability is usually lowered, and sensation is blunted, whilst the tendon reflexes are increased.

Hysterical paralysis is often associated with flexor rigidity instead of flaccidity. In hysterical rigidity the forearm, hand, and fingers may be brought into the same plane by coaxing and manipulation. In organic rigidity this is impossible.

2. Mechanotherapeutics.—When early rigidity is marked and progressive, the constant tendency to flexion of the elbow, with pronation of forearm and flexion of wrist, should be treated by applying a back splint to the limb, care being taken to avoid undue pressure.

Flexion of the fingers and thumb only may be combated by placing india-rubber balls, graduated in size, in the palm of the hand. When raising the heel and buttocks fails to remedy flexion of the hip and knee, an extension apparatus should be applied, whilst sand-bags are used in order to counteract rotation inwards of the limb, and a "Scarpa's" shoe to obviate plantar flexion of the foot. Such apparatus should be used only so long as the patient is confined to bed. As soon as he is able to get up, the appliances should be worn at night only, and by day passive movements should take their place. When possible these should be carried out by the patient himself.

An excellent exercise for a patient with a paralyzed and stiffening arm is to interlace the fingers with those of his other hand, and then, helping the paralyzed by the sound limb, to imitate the movement of rowing with both. Thus the contracted fingers are expanded, the wrist and triceps extended, and the biceps relaxed, in one procedure.

3. Massage and Electricity.—Massage arrests atrophy, promotes muscular growth, prevents œdema, improves the circulation of blood and lymph, renders the joints supple, and probably has a direct action on nerves and nerve centres; but massage, unless employed with gentleness and intelligence, does more harm than good. It is useless to leave a masseur who has learnt the mysteries of *effleurage*, *pétrissage*, *tapotement*, and *hachage* in six easy lessons, to work his will on the patient. The crude methods of the ordinary shampooer are not applicable to the sufferer from hemiplegia.

Having secured the services of a competent masseur, we have yet to teach him what to do. It has already been mentioned that spasticity tends to affect certain muscles more than others, and that those most affected may become permanently contracted. Contracting or contracted muscles should never be forcibly stretched, but be coaxing to relax by gentle steady traction and stroking (*effleurage*). Rough kneading (*pétrissage*) and thumping (*hachage*) stimulate muscles to further contraction, and therefore should not be applied to those which are already in hypertonic condition. On the other hand, the more vigorous methods of massage are useful in improving the tone of individual uncontracted muscles, and thus enabling them to counteract their contracting opponents. *Effleurage*, or stroking, promotes general circulation in the limbs. A combination of centripetal and centrifugal massage is perhaps most efficacious. The efficacy of massage is increased by previous

immersion of the limbs in a warm bath. Cold always aggravates rigidity, and it is essential to keep paralyzed limbs warmly wrapped with cotton-wool or Jaeger from the first.

Electricity, whether faradic or galvanic, is a useful adjunct to massage, but cannot take its place. If faradism and galvanism have been discredited in the treatment of hemiplegia, I believe it is because so-called "medical electricians" are sometimes over-anxious to give the patient his money's worth. The currents which they employ are often far too strong, their negative electrodes are too small, and they alarm and hurt the patient by sudden makes and breaks. Any current which causes pain or produces powerful muscular contraction is too strong, and may do harm.

In old-standing cases, with advanced structural contraction of muscles, electricity is practically useless. Neither faradism nor galvanism should be used until five or six weeks have elapsed since the onset of cerebral hæmorrhage; for the patient is usually in a weak, agitated, and emotional condition during this period, and any sudden pain or shock may determine a fresh attack.

In early rigidity, mild faradism to the extensors and other muscles which show no signs of contraction is, I believe, of service in promoting their strength and nutrition. But any current strong enough to make them contract forcibly may produce a similar effect on their opponents, which is undesirable: the current should, therefore, be sufficient to excite only slight muscular reaction.

Galvanism may perhaps allay spasm of muscles, and, theoretically, should be applied (the anode mobile) to contracting muscles only. Weak currents only of 1 to 5 ma. are admissible; sudden makes and breaks should be avoided; the currents should be turned on and off gradually, and electrodes should be large, especially the stable one. No *séance* should exceed ten minutes, once daily, at first, the period and frequency being cautiously increased. The utility of galvanism is, however, problematical; central galvanism of the cerebral nerve centres, with a view to "re-charging the cells with activity," is of therapeutic value only in proportion to the patient's credulity. If the patient professes himself the better for it, he probably feels so, although the improvement may not be apparent to the outside world.

4. Re-education of Movements and Therapeutic Suggestion.—So far we have considered the physical causes which impede recovery and the methods of attempting to avert adhesions, late rigidity, and muscular atrophy. It must be admitted that in severe cases treatment at best is only palliative. Complete recovery cannot be expected when a large part of the cerebral motor tract is absolutely destroyed. Yet we can never tell the amount of destruction which has occurred until time has elapsed. The symptoms of an organic lesion are always widely in excess of its extent, so the prospects may not be so hopeless as they appear; even in the worst cases, a certain amount of improvement may be expected, and its degree will depend on the extent of the damage. We can usually estimate this in a few months' time by the amount of spasticity and atrophy which prevails. Generally speaking, the less the spasticity and wasting the better the prognosis. Motor paralysis is of less grave significance than spasticity.

Occasionally one meets with cases in which, although adhesions, spasticity, and atrophy are slight, or even absent, no improvement is manifested. After many months, or even years, the patient remains as helpless as at first. The reason may be that the patient is unaware that any restoration has taken place. He does not try to use the powers which he has unconsciously regained. He is too depressed and disheartened, too apathetic and resigned to his misfortune, or too timid to attempt to help himself. Apart from such mental conditions, which of course need appropriate treatment, he seems literally to have forgotten

how to execute voluntary movements. In re-educating him we are helped by knowledge of the natural order in which recovery occurs. Thus, the leg usually recovers before the arm, the hip and knee before the ankle, the shoulder before the elbow, the elbow before the wrist, whilst the extensors of the fingers, and especially the abductors and extensors of the thumb, are the last to be restored. The rule is that the parts whose movements are most specialized and least associated with movements of the opposite limb are the last to regain power. This knowledge is most valuable, for if we can foretell to the patient that power will return in due order in each limb or joint, and he finds the prophecy true in one instance, he will gain confidence in its truth as regards the rest, and will persevere in his attempts to anticipate progress. He is less apt to mourn over his useless fingers if able to rejoice over a serviceable leg. Therefore we endeavour to fix his attention on the parts which should be recovering rather than on those which are still obviously paralytic. He has to be content to sit up before he can stand, to stand before he can walk, and to move his shoulder before his elbow, his wrist, and his digits; but he will often be unable to regain any of those powers unless literally taught to do so. The method of teaching is to foresee the dawning approach of power and to elicit it by means of passive movements. It is useless merely to tell such a patient to elevate his arm at the shoulder. He will only sign, "I cannot"; but tell him to do so, and at the same time do it for him, and he will gradually learn to raise it himself. At each attempt the operator does less and the patient does more; so the essence of re-education is in the use of passive and active movements combined.

This principle may be applied in the re-education and amplification of all movements. For instance, a patient has learned to walk, but complains that "one foot is always walking into the other and tripping him up." On examination we find that he always sits with his knees and toes turned in. He is unaware of the necessity for practising abduction, rotation outwards, and eversion of the limb, and he is quite unable to execute these movements until taught by passively working the thigh and the foot, and encouraging him to make voluntary efforts to do so at the same time. Similarly, although he knows how greatly foot-drop interferes with his walking, he will not try to dorsiflex his foot unless persuaded. He must be taught to make the effort whilst sitting, helping himself meanwhile by pulling on a strap attached to the fore part of his foot. Or, again, he has never learned to use his hip flexors. He circumduets his leg, or drags it behind him, and has difficulty in getting upstairs. We may teach him to flex his hip on the same principles. When some power has been regained, it may be improved by making him stand, holding the back of a chair, and then directing him to place his affected foot on the rungs, from the lowest upwards. Koundjy uses miniature staircases for this purpose.

Disordered Association.—The normal *alternate* association of leg movement in walking is often impaired and perverted after hemiplegia. The patient may appear to try to move both legs forward at once. Directly he advances the sound limb the affected one becomes rigid, and is dragged painfully behind. To lessen the difficulty he should be taught to advance the unsound leg before the sound, bringing the latter up to the level of the former after each step. He needs to be lightly supported on the paralyzed side by an attendant, otherwise he will not rest on the affected leg for fear of falling. It is desirable to prevent a fall, of course, but the support which is given should be moral rather than physical. For this reason, the help of an attendant is preferable to that of a stick or crutch. The patient, if able to use either implement, is apt to make it a substitute for his weakened leg instead of an adjuvant.

Ataxy.—Want of precision in movements often follows recovery of both limbs. Exercises on the Fraenkel system for the treatment of locomotor ataxy are useful

in such cases. Games such as draughts, halma, or solitaire may be recommended, or targets may be constructed on which the patients practise, touching the bull's-eye and various circles with the forefinger, or the "Digitarium" or dumb piano may be used. Practice on a typewriting machine has the advantage of being useful as well as remedial. For ataxy of the lower extremity, Fraenkel's various apparatus may be used whilst the patient is lying in bed. He should also stand, supported by the back of a chair, and then, resting on his sound leg, place the foot of his weak one into wooden curtain rings or chalk marks placed in various positions on the floor, touching each in turn as directed.

Apraxia consists in inability to perform at request ordinary actions, such as shaking hands, beckoning, etc., although there is no motor paralysis and the patient perfectly understands what he is asked to do. Liepmann attributes it to interruption of the connections between the cortical centres for the execution of voluntary movement and the sensory centres that lie around them. The outlook is not hopeful, but re-education may perhaps be of service.

SUMMARY.

1. Neglect and want of treatment aggravate severe, and retard the recovery of mild, cases.

2. The evils to be foreseen and guarded against are articular adhesions, late rigidity, and muscular atrophy.

3. Articular adhesions should be prevented by passive movements of each joint from the very first.

4. Faulty positions of the limbs should be constantly corrected, or they will become chronic.

5. Contraction of muscles should be treated by endeavours to improve the nutrition of their uncontracted opponents.

6. Massage, passive movements, and, to a less degree, electricity, should be used with this object. These agents not only counteract muscular atrophy from disuse, but probably take the place of normal stimuli and invigorate the neurons.

7. The recovery of mild cases may be often hastened by re-education of movements. Want of re-education frequently prevents recovery.

8. Re-education consists in a combination of passive and active exercises.

9. Movements should be encouraged first in those parts which naturally tend to recover first.

10. Inco-ordination, and general weakness of limbs which have yet regained power of movement, should be treated by exercises and mechanical therapeutics.

11. It is important to find out what the patient can do, and to make him do it.

In conclusion, this article deals with the treatment of hemiplegia as a condition, without reference to its cause, for whether the cause be hæmorrhage or occlusion of cerebral vessels by embolism or thrombosis is immaterial; the principles of treatment will be the same, and need not interfere with other measures taken for the relief of the disease which gave rise to the hemiplegia. (See also APHASIA; APOPLEXY; ELECTROTHERAPEUTICS; PALSIES, CEREBRAL, OF CHILDHOOD; PARALYSIS.)

Leonard G. Guthrie.

HEPATIC ABSCESS.—If the presence of a hepatic abscess be suspected, the liver must be explored with an aspirator needle, for the earlier the abscess is drained the better are the prospects of recovery. A full-sized aspirator needle should be used, for the pus may not pass through the smaller needles.

When localizing signs are present over any particular area of the liver, puncture should be performed at this spot; otherwise the needle should be

inserted through the 8th or 9th intercostal space in the mid-axillary line, and passed towards the upper and posterior part of the liver. If this should fail to find pus, Sir Patrick Manson recommended that at least five other punctures should be made before the attempt to discover pus is abandoned.

OPERATION.—The abscess may be reached either through the abdomen or through the chest wall; most abscesses are situated in the upper and posterior part of the liver, and for these the thoracic operation is preferable.

In the abdominal operation the incision is made through the outer part of the right rectus muscle; the peritoneal cavity is carefully packed off with gauze, unless already shut off with adhesions. The greater part of the pus is removed with the aspirator, the abscess cavity is then opened with a fine scalpel and the finger, and a large tube is inserted. The cavity should not be scraped or irrigated.

In the thoracic operation, a portion of the 9th, 10th, or 11th rib is resected in the scapular line; if the pleural cavity is opened, the upper portion should be closed off with a continuous suture or gauze packing; fibres of the diaphragm are then divided, and the abscess dealt with as in the abdominal operation.

T. Crisp English.

HEPATITIS.—In simple hepatitis, rest, and absolute avoidance of alcoholic stimulants and of highly spiced food, are most essential. Diet should be restricted to milk and farinaceous food. Free purgation by calomel, followed by saline aperients, will, as a rule, rapidly reduce the severity of the symptoms.

After such an attack, the diet must be carefully regulated for months, alcohol avoided altogether, and any tendency to constipation corrected by the use of natural waters. Exercise in moderation is to be recommended.

The local application of iodine and biniodide of mercury, or large hot applications, may be used if any tenderness or enlargement of the liver be present. The abdomen must be protected from chill, particularly when the patient is not in bed.

The possibility of the hepatitis being malarial must be considered. If a blood examination shows that there is malaria, quinine in full doses must be given. In the hepatitis associated with dysentery, or where there is a history of dysentery, a course of ipecacuanha or emetine will be most effective. Even if there is no evidence of dysentery, a course of emetine hydrochloride injections should be tried.

C. W. Daniels.

HERNIA.

Non-operative Treatment.—This applies only to cases of reducible hernia, operation being generally indicated in cases of strangulated or incarcerated hernia. Treatment consists in preventing the hernia from coming down, by means of a properly fitting truss. It is essential that the truss should retain the hernia at all times and under all conditions, since if it comes down behind the truss the patient is in more danger of strangulation than if none is worn. The patient should have three trusses. One will be for use during the day-time, and one at night; the latter can have a lighter spring, or may be of the type known as the Moe-main lever truss, as there is not the same tendency for the hernia to come down at night; he should also have a third appliance, made of rubber or celluloid, for use in the bath, during which there is a special tendency for the hernia to come down. To prevent the truss becoming soiled, a removable linen cover should be made for it; some patients prefer to wear the truss over a thin vest. It is always advisable to wear the truss day and night. A great deal of the success of a truss depends upon its fitting properly, and the doctor ordering it should satisfy himself on this point. If after the truss has been worn for a few days it still causes discomfort

or pain, this is generally due to a fault in the fitting or too strong a spring, and it should be altered accordingly.

Chances of Cure by Truss Treatment.—Though it cannot be said that a cure of the hernia never results from wearing a truss, this is so seldom the case that it is not worth considering, and if the patient decides to wear one he must be prepared to do so for the rest of his life. In infants and children a cure of the hernia more often results from truss treatment; but it is most uncertain, and only too often the hernia recurs when the child reaches adult life and the parts are subjected to greater strains.
